We offer for consideration that just because Meltzer showed that the physiological action of magnesium sulphate solution is relaxing to the unstriped muscle fibres is no reason to deduct in the method that the Odii sphincter is relaxed by it and a "crossed innervation" need be hypothesized because characteristic B fractions are obtained. Many other substances than magnesium sulphate will give the characteristic B fraction (peptone solution, dilute HCl, etc.) It is our opinion that the presence of a stimulant to the duodenal mucosa initiates and continues the flow either reflexly or through secretion energizing the biliary channels in the liver to discharge their contents. However, here we feel that the severe symptoms were due to the chronic appendicitis which the high unit reading of the Bassler test tends to prove by eliminating the gallbladder as a cause. We think it is too soon to decree that the Bassler test is infallible although in our experience it has been remarkably steady and dependable for a laboratory procedure and as a standard to judge accurately the effect on the pancreas from existing gallbladder pathology.

Crohn and others have suggested that even with chronic pancreatitis the enzyme function may be normal. Experience with depancreatized dogs has

proven that the merest shred of pancreatic tissue left *in situ* will function surprisingly well, keeping the animal in digestive balance. From far too limited observation thus far obtainable to be sure about it, a few cases have given us the suggestion that abnormal conditions of the head of the gland give deficiency findings while those of the body or tail alone are not liable to. A recent article by Piersol and Bockus (3) on this subject suggests that in a group of cases of gallbladder disease eighty-five per cent. showed a reduction of over fifty per cent. in enzyme activity, which we feel is far too high an association and due entirely to the method of testing the duodenal return employed. Our observations on this point comprise too few proved operative cases to report at this time. But up to the present it seems logical for us to state that somewhere between twenty and forty per cent. is more accurate as to clinical fact and this corresponds more closely to the figures of Judd (4) and other surgeons as to the incidence of associated pancreatitis or stiffening of the head of the pancreas met with at operation in which gallbladder pathology was proved.

The following is a case of chronic cholecystitis with reflex hypopancreorrhea, negative bile aspiration, reason for operation.

Case VIII.—Mrs. C. V. M. The patient was referred by Dr. S. W. Wells, Liberty, New York, October 27, 1924; married, no children, aged thirty-one. The family history was negative. The personal history was negative except for an appendectomy ten years before, for acute appendicitis, and pneumonia six years before. Present illness: At the time of the operation on the appendix the patient was seized with an acute pain in the right abdomen which was diagnosed as due to gallstones. At operation the gallbladder was found normal, but the appendix was found acutely inflamed and removed. Off and on since that time the patient had some slight distress on this side which was not of importance until four months ago, when it became troublesome. Operation was again advised on the diagnosis of acute inflammation of the gallbladder. At times in the past years the patient had had sugar in her urine and excess sugar in the blood, both of which were easily controlled by diet, so that at the present time it was deemed of little significance and no special diet was being followed.

The physical examination was negative except for a slight degree of anemia which was confirmed in the laboratory. There was also considerable debility. X ray examination was negative with the exception of a visible gallbladder, the suggestion of postpyloric adhesions, and a distinct tenderness over the gallbladder. The urine was negative and the bile aspiration also, except that there was but six units pancreatic efficiency by the Bassler test. For treatment, cholecystectomy was advised, followed by pancreatic feedings of pickled whole gland.

Progress: An operation was performed on November 5, 1924, by Dr. J. B. Hulett of Middletown, New York. The gallbladder appeared normal but twisted on itself and bound down by many adhesions. The organ was removed. Recovery was rapid and the symptoms disappeared. A pancreatic efficiency test done February 27th showed eighteen units, demonstrating resumption of pancreatic function.

Comment: Here is a case of chronic cholecystitis with a negative diagnostic bile aspiration but in which there was depressive dysfunction of the pancreas, reflex from the gallbladder. In this case no pathology would be found in the pancreas largely because no marked or at least no demonstrable infection of the bile tract existed. Recall that the gastric factors of infective bile tract or gallbladder disease are missing in the history. A reflex depressive function on the pancreas from the gallbladder where there is enough suggestion from physical and x ray examination always suggests the performance of a cholecystectomy.

In the next case cholecystectomy for stones was performed. The symptoms continued due to enterocolonic stasis, redundant sigmoid, ptosis and intestinal toxemia. By virture of the test the pancreas was judged as normal and thus no resident pathology from the pathology of the gallbladder.

Case IX.—Mrs. D. P. The patient was referred by Dr. A. Sturmdorf, New York; she was a housewife, aged thirty-five, with one child. Her father and mother were living. She had had a gynecological operation five years ago, and the gallbladder was removed one year ago on account of severe attacks of biliary colic requiring morphine injections. She had had more or less indigestion since the removal of the gallbladder, but more attacks of pain. This apparently was not in any way due to the operation on the gallbladder, because some symptoms existed before and were masked and made light of with the more prominent attacks of biliary colic. About ten days or two weeks before menstruating, the patient felt vague pains through the body, cardiac palpitation, exhaustion, and the indigestion was worse. However, there was more or less indigestion all of the time, and she was habitually constipated.

Physical examination showed a contracted chest, of the atonic type; the abdomen very poorly developed; the stomach and cecum splashy; the stomach distinctly low on standing; the Sargent white line positive; metabolic rate plus eight, and blood pressure 100/80. The x ray examination disclosed a moderate grade of ptosis with good motility, marked ideal statis, redundant sigmoid, general tenderness in epigastrium. The urine was negative except for excess indican and a 10.3 sulphate partition. The stool examination showed a high coli content, alkaline reaction, and the typical laboratory picture of an intestinal putrefaction. The bile fractions on June 25, 1924, were: A, 70 c.c., light yellow, clear, mucus x, pus x; B, 120 c.c., dark amber, mucus xx, pus xxx, many clumps of bilirubin, some cholesterin crystals; C, 30 c.c., yellow, clear, mucus x, pus x. The Bassler test reading was fifteen units. Treatment was for the conditions mentioned, consisting of constructive and anti-constipating diet, a belt, reconstructive exercises, ovarian substance, and the correction of social and domestic troubles. The result was most satisfactory.

Comment: Here is a case that gave a positive B fraction in the bile aspiration as to pathology although the gallbladder had been removed. The positive nature of the B fraction was paid no attention to in the presence of a normal unit reading. The case illustrates that even in the presence of an adynamic type of body and vitality and a toxic intes-

tine the pancreas functions normally. It is presented to show a point we think important, namely, that an infectious gallbladder pathology may by congestion of the head or actual disease of the pancreas cause a hypopancreorrhea and, in this instance, unless the disorder in the pancreas has become too far organic, operation is always justified because a good many symptoms which heretofore have been considered due to indigestion from the gallbladder are really the result of low pancreatic function which in the congestive cases is restored to normal by cholecystectomy. It is also true that there may be no hardening of the head of the pancreas possible of being felt when marked infective pathology of the gall tract exists, especially of the gallbladder. In this instance the pancreas is not affected, and if the gallbladder had not been removed it would have been a matter of judgment when the unit reading is normal as to whether an operation should be performed or the condition treated by medical means. It is apparent in this case that the patient had other causes for abdominal distress and that these were the more important, but helping in judging this was the normal pancreatic test.

The following case is carcinoma of the gallbladder and pancreas in which the bile aspiration showed the presence of bile while a marked jaundice existed but the pancreatic test was positive.

Case X.—Mr. I. J. The patient was seen on June 27, 1924. He was a retired business man, aged fifty-six, married, six children. His family history showed that his father and mother were dead, causes unknown; several brothers and sisters were living and considered well. The personal history was negative. Without having any previous illness or indigestion the present illness began with jaundice about nine months ago. The urine then became dark and the stools light. Slowly there developed a feeling of weight and pressure in the upper right abdomen. He had lost twenty pounds in weight during the last nine months, and during the past few weeks the feet became swollen. Physical examination showed the patient markedly jaundiced, somewhat emaciated, with a hard irregular mass in the upper center of the abdomen, mostly springing from the upper left side. There was a slight edema of the ankles. The laboratory reported the urine markedly bile stained, and the stool acholic. Careful examination of the stool showed a very moderate steatorrhea. Bile aspiration gave A, B, and C fractions in amounts of 20, 15, and 12 c.c., respectively. Each was bile stained although all of them were but faintly so compared to routine returns. In the Bassler test there were no pancreatic units. On July 2, 1924 the abdomen was opened and an extensive carcinoma involving the whole head of the pancreas and the gallbladder was discovered. The patient died November 3, 1924, from advanced carcinoma.

Comment: Here is a case which suggests a point that any involvement of the head of the pancreas (which in bulk is about one half or two thirds of the organ), whether from syphilis, tuberculosis, malignant disease or chronic pancreatitis generally, gives negative or very low pancreatic readings in the test. It shows that bile may occasionally be aspirated from the duodenum in marked chronic jaundice and yet the pancreatic efficiency test be positive as to involvement of the pancreas.

Office Gynecology*

SAMUEL BERNARD SCHENCK, M.D., F.A.C.S.
Brooklyn

This subject is so broad that I shall touch only a few of the high spots and lay emphasis on some of the more common and practical aspects.

Excluding neoplasms and venereal infections, the major part of gynecology is the result of poor obstetrical work. Among these causes are manual dilatation of the cervix, the abuse of pituitrin, artificial rupture of the membranes before dilatation is complete, instruction to the patient to bear down before dilatation is complete, the premature and improper use of forceps, improper repair of lacerations of the pelvic floor, suturing the skin and not the muscular structures, and improper asepsis with its chain of sequelæ.

The history of the gynecological patient is extremely important. Emphasis should be laid on the menstrual history. A late onset, for example, may lead us to suspect infantilism. The date of the last period and of the one before that should always be taken. The obstetrical history should be taken in detail. A long period of time in bed postpartum will suggest a puerperal infection. The incidence of miscarriages should be noted and also whether curettage was performed and if infection occurred. The triad of gynecological symptoms, pain, discharge and menstrual disturbances, should be inquired into in detail.

A complete physical examination should be made. In the vaginal and rectal examination the finger should be covered with a glove or finger cot. The cervix and vagina should he inspected through a speculum. No gynecological examination is complete unless a rectal examination is done.

I should like to emphasize that the diagnosis of a pathological condition found by this physical examination is not enough to make a decision regarding therapy.

When a lesion like carcinoma or ovarian cystade-

*Read before the Bayonne, N. J., Medical Society, January 26, 1925.

noma is discovered the course to pursue is simple, regardless of the presence or absence of symptoms. The examiner may discover fibroids, pyosalpinx or other conditions not endangering life but endangering the future health of the patient and therapy must be instituted. However, in the course of his pelvic examination the examiner may find minor divergences from the normal which frequently have no relation to the pain, or other symptoms complained of. Successful treatment in gynecology will depend not only on the correct diagnosis of a pathological condition of the pelvis but also on a proper study of the patient from all angles. For example, a woman complaining of backache and weakness may have a lacerated pelvic floor and a lacerated cervix but the symptoms may be due to her having had several children in rapid succession. She may do an excessive amount of washing and be very tired. To correct this woman's pelvic pathological condition and not her social pathological condition should be considered a mistake in gynecological judgment.

While we are definitely certain of the value of ovarian and thyroid therapy in the climacteric and in hypothyroid conditions, therapy with the other gland must as yet be considered in the experimental stage. The results assumed are far from proved and glandular therapy will often cause disappointment. We may say that the ovary and thyroid are counterbalanced by the adrenals and pituitary; that thyroid is to be given to the fat, sluggish woman; that ovarian substance or ovarian residue is to be used in amenorrhea and during the menopause; that pituitary and mammary glands are of value in the bleeding from subinvolution and in the moderate idiopathic bleeding in young girls; that corpus luteum is of some value in hyperemesis gravidarum, vicarious menstruation, and habitual abortion; that pituitary may be used in dystrophia adiposogenitalis, and that placental extract has been used for hyperemesis gravidarum, with, however, varying results.

GONORRHEA

The gonococcus causes a large portion of pelvic pathological conditions, spreading by direct extension along the cervix, uterus, tubes and peritoneum, causing also a urethritis but fortunately rarely a cystitis. A few facts regarding therapy may be emphasized. In the acute stage, rest in bed, a bland diet, tincture of hyoscyamus or balsam of copaiba internally, opium suppositories when necessary, and intraurethral injections of one or two per cent. protargol solutions may be used, care being taken not to enter the bladder. Warm sitz baths are useful. After subsidence of the acute stage the chronic urethritis should be treated with five per cent. silver nitrate solution directly applied through a Kelly endoscope, and vaginal douches of potassium permanganate solution may be advised, the douche being given under low pressure. While the cervix has been treated with silver nitrate, tincture of iodine, methylene blue, mercurochrome, and other drugs, I have found the most effective weapon to be the electric cautery applied in linear cauterization. It is important to treat Skene's and Bartholin's gland. A five or ten per cent. solution of silver nitrate may be injected through a hypodermic syringe, but here also the electric cautery will give greater assurance of eradication of infection.

In regard to adnexal involvement in the acute stage, the patient should be kept in bed with an ice bag to the lower abdomen, and the head of the bed should be raised. Plenty of fluids should be given to the patient and enough opiates to relieve the pain. Foreign protein therapy, such as the injection of milk, has been recommended, but I have had no experience with it. Intravenous medication and vaccines have been found useless. In the subacute stage, prolonged applications of heat, hot douches, hot sitz baths and dry heat externally will be of great help. During menstruation, the patient should be kept in bed and all treatment suspended. Conservatism is the watchword in adnexal gonorrhea, the longer operation is postponed, the less will have to be sacrificed. It is remarkable how the most involved pelvic pathological condition will clear up under conservative treatment. However, after months have passed, particularly in a woman whose earning capacity must be restored, if pain persists operation must be performed. The patient should be pronounced cured only if several smears from the cervix and from Skene's and Bartholin's glands are negative to gonococci and remain negative after menstruation, after a hot bath and after coitus with a condom. In the vulvovaginitis of young children, the vulva should be bathed frequently and a twenty per cent. argyrol solution introduced into the vagina, or through a triumph syringe with a small rubber tube attached, a one per cent. silver nitrate or mercurochrome ointment should be injected. The curette has no place in the treatment of gonorrhea.

LEUCORRHEA

Leucorrhea is the ever present complaint of the gynecological patient. It may be due to tumors, foreign bodies in the vagina introduced for the prevention of conception, or for masturbation, or forgotten pessaries, and is often the first sign of malignancy. In the majority of cases, however, it is the result of an inflammatory lesion of the racemose nabothian cervical glands. Bacteria, acting on a cervix recently lacerated during delivery or miscarriage, or on a cervix the seat of congestion from displacement or coitus interruptus, will cause this endocervicitis. In this condition the cervix alone is the cause of the leucorrhea and the inside of the uterus is not to be entered. Tampons are useless here no matter with what medicament they are impregnated. The cervix may be treated with silver nitrate, tincture of iodine, various powders, or other medication, but the best results will be obtained by the use of the electric cautery, linear incisions being made in the anterior and posterior lips. Douches should be used for cleansing purposes. The curette has no place in the treatment of leucorrhea. In the unmarried, congestion from constipation, displacement of the uterus, masturbation or from general debilitating conditions is the usual cause. Daily bathing is necessary, followed by a sterile douche through a soft rubber catheter and the instillation of a powder such as kaolin. Attention should be paid to the general health of the girl, outdoor exercises advised, and the syrup of the iodide of iron may be given internally.

BACKACHE

Another never ending complaint of the gynecological patient is backache. What is a simpler conclu-

sion in a patient who has the combination of backache with a retroverted uterus than that the retroversion is causing the backache? And in how many cases do we see women with uterine suspension who have had no relief! Exclusive of a pelvic pathological condition, backache may be due to sacroiliac subluxation, flat feet, faulty attitude, spinal curvature, spinal cord disease, and other causes. The normal mobility of the sacroiliac joints is increased during pregnancy and it is then and after delivery that sacroiliac pain is most likely to occur. Firm strapping with strips of adhesive plaster two and a half to three inches in width from the anterior superior spine of one side around the back to the other side and from the femoral trochanter around to the opposite one will keep the joints firm and relieve the pain. Then a properly fitting sacroiliac belt should be worn. Flat feet should not be overlooked. A coccygodynia will be met with occasionally, particularly after traumatism from prolonged labor or forceps delivery, or after falls or kicks. This can often be relieved by hot sitz baths and counterirritation. Rarely will excision of the coccyx be necessary.

The chief pelvic causes of backache are retroverted and retroflexed uteri and uterosacral cellulitis. Before operating to relieve a backache believed to be due to a retroverted uterus, the uterus should first be replaced manually and held in anteversion by a suitable pessary. The uterine sound has no place in the diagnosis of retroversion and should never be used to lift the uterus back into normal position. If the backache is relieved by the pessary we are justified in our conclusion as to cause and effect and may permanently cure the patient by a suspension operation, at the same time repairing any lacerations that may exist. Endocervicitis will cause extension of inflammation along the uterosacral ligaments and cause backache. In this case vaginal examination will reveal two tense and tender bands extending posteriorly from the cervix. The endocervicitis should be treated, preferably with the electric cautery, and heat in the form of hot sitz baths and hot douches will relieve the cellulitis.

UTERINE DISPLACEMENTS

The question of displacements of the uterus is most interesting when considered from the point of view of a prognostic diagnosis. The diagnosis should rightly include not only an anatomical and pathological diagnosis but also a prognostic diagnosis. Are the patient's symptoms due to the displacement and will she be well after the displacement is corrected? This is especially important if an operation is contemplated. A thorough physical examination should be made and the history should delve into the patient's mode of living where we can often make corrections that will bring about a symptomatic cure. It may be in place to remark that patients after operation should be instructed as to how to live, for only two often do we see women with beautifully repaired pelvic floors and cervices and uteri suspended in perfect position who a month or two after operation living and working as before will have a recurrence of all their symptoms. It is the physician in general practice who sees the woman in her normal habitat for a long period of time who can best make this prognostic diagnosis.

Office therapy of displacements of the uterus has a definite and useful field. In the retroversion in young girls resulting in menstrual disturbances, pelvic congestion, leucorrhea and pain, outdoor sports and exercise, the knee chest position, the kangaroo walk, attention to the bowels and instruction to empty the bladder at frequent intervals will often result in a cure. In the woman, especially postpartum, the large, subinvoluted retroverted uterus is often seen. Routine use of the knee chest position or the kangaroo walk postpartum will prevent a large proportion of these cases. When the uterus can be reposited by bimanual manipulation a properly fitting Smith or Hodge pessary should be inserted to keep it in position. This will relieve the congestion and subinvolution, the uterus will become smaller and after a few months the condition will be permanently cured. These patients should be instructed to take a daily cleansing douche and should be seen in the office once a month when the pessary should be removed and the vagina inspected for areas of ulceration. If there are any they should be treated and when healed a properly fitting pessary reintroduced. If there are no points of irritation the original pessary should be reinserted. A properly fitting pessary should cause no discomfort and should not interfere with coitus.

In the true adherent retroversion, operation is the only means of cure.

A prolapse of the uterus once established can be cured only by surgical treatment, but this condition frequently occurs in old women who are poor operative risks for various reasons and we are forced to do whatever is possible with pessaries. If reposition is difficult, the patient should be kept in bed and hot applications used until the prolapse can be reduced. A hard rubber pessary should be inserted, the biconcave discs, the Menge pessary which has the projecting bar lying in the vagina to prevent displacement of the pessary, or a combination of the ball and cup pessary being used. When the condition is so bad that a pessary cannot be retained some sort of abdominal binder with a pessary held in place by straps like the Mackintosh contrivance must be used. The soft rubber pessary should never be used as it is a pusformer. These pessaries should also be removed every month and the vagina inspected for areas of ulceration before reintroduction. The patient should be instructed to bathe and douche daily.

DYSMENORRHEA

Dysmenorrhea is at times difficult to handle. We should determine whether the pain is premenstrual or comenstrual, steady or colicky. This will occasionally result from evident pathological factors such as fibromata, retroflexion, or other conditions. In ovarian conditions it is an increase of a steady pain the result of a thickened tunica albuginea through which the matured Graafian follicle has difficulty in bursting. Sometimes this type is seen only every other month. Sometimes there is an ovarian toxemia with resulting change in what some authors are pleased to call the endometrial ferment as a result of which the blood clots, expulsion of the clots causing pain. The spastic type of dysmenorrhea is that in which the normal painless uterine contractions become so strong that pain results. In the congestive type pelvic inflammation or congestion from con-

stipation, coitus interruptus or masturbation may be the offender. The obstructive type is rare but occasionally where there is a sharp anteflexion, thorough dilatation followed by the introduction of a glass stem pessary to be retained during four menstrual periods will bring relief. This procedure is, however, by no means a panacea for dysmenorrhea, as it is indicated only rarely and even then recurrences occur. All evident pelvic pathological conditions should be corrected but it is in the case where no pathological conditions can be demonstrated that the difficulty arises. Especially in young girls, outdoor sports, abdominal exercises and attention to the bowels are important. In the spastic type belladonna or benzyl benzoate will often give relief, especially when the drug is given for a week before menstruation, increasing the dose at the onset. Aspirin, pyramidon with caffeine, may help. All sorts of combinations of the endocrines have been suggested but ovarian or corpus luteum in combination with thyroid in the obese are of value.

Nasal therapy should be mentioned for a rare case is seen particularly among nervous young girls who have colicky pain after the onset of the flow with headaches, vomiting and dizziness which is relieved by the application of a solution of two parts of ten per cent. cocaine and one part of one to one thousand adrenalin to the lower turbinates and nasal septum by applicator or spray.

STERILITY

The subject of sterility is worthy of a few remarks. It is essential that the male partner be examined in every case. The first procedure to be done in every case is the Huhner test. The patient should come to the office soon after coitus and a few drops of semen aspirated from the region of the cervix should be examined under the microscope. In healthy individuals dozens of active spermatozoa are seen in one low power field. Sometimes spermatozoa are seen entangled in mucus or killed by an acid vaginal discharge in which case simple alkaline douches may effect a cure.

It is also important especially in old healed gonorrheal cases to determine the patency of the Fallopian tubes. Instead of the original Rubin method the following modification may be used. A Keyes-Ulzman metal catheter is passed through a rubber urethral tip and is attached at the other end to a piece of rubber tubing, the urethral tip being one and a half to two inches from the tip of the catheter to plug the cervical canal. The rubber tube is then attached to a three way glass tube, the other two ends of which are connected by rubber tubing to a mercury manometer and to a large Luer syringe. The entire outfit, except of course the manometer, is sterilized by boiling. Through a bivalve speculum the cervix is drawn down by a tenaculum, cleansed and painted with tincture of iodine. By a sound the length and direction of the uterine canal are determined and the metal catheter inserted, the rubber urethral tip plugging the cervix. Atmospheric air is drawn into the Luer syringe and slowly injected into the uterus. Air will pass through the tubes under a pressure of 40 to 100 mm. mercury. If the pressure rises to 150 and remains there the tubes are closed. When air does pass through shoulder pains will occur in a few minutes. If desired an x ray will show the presence of air in the peritoneal cavity. This procedure, while important, is not without its dangers and should never be used in the presence of acute or subacute infection. Cases will occasionally be seen of acute exacerbation of chronic pelvic inflammation caused by the Rubin test.

It is in the case where the spermatozoa are active and the tubes are open, where we can find no pathological condition and sterility still persists that we have our difficulties. Sometimes we find fat, flabby women of definite hypothyroid type that calls for thyroid therapy. All sorts of combinations of endocrines have been advised, the combination of ovarian or corpus luteum with thyroid being the favorite. When, however, we see as I did a short time ago a woman of forty having her first baby in the fifteenth year of married life, having never used any contraceptive measures and having never had any treatment, it behooves us to restrain our enthusiasm when we see an occasional pregnancy follow our favorite treatment. The curette has no place in the treatment of sterility, and neither has dilatation of the cervix. Any cervical canal large enough to permit the passage of menstrual blood is large enough to permit the passage of spermatozoa. In general, operations for sterility *per se* are inadvisable.

CONCLUSION

In this brief talk, I have omitted many subjects and emphasized only a few. In closing, permit me to add my admonition to what you have doubtless heard many times. With the men in general practice lies the responsibility of making an early diagnosis of cancer of the uterus and so reduce the tremendous yearly toll of this disease. Whether the treatment be surgical or by radium and the röntgen ray, the early diagnosis is the vital factor. The malignant change may go on for some time without the patient being aware that anything is wrong. There is at first a slight serous transudation, often unnoticed, followed by what is really the first danger signal, a tinge of blood after coitus, a constipated stool or after a douche. Examination will disclose a mass springing from the cervix only in the squamous type, while the adenocarcinoma arising within the cervical canal and the carcinoma of the body of the uterus may give no signs. Here the curette has its distinct field and a diagnostic curettage of the entire interior of the uterus followed by a microscopic examination of the scrapings will give the diagnosis.

We must remember that the change of life is gradual and not ushered in by hemorrhages, and that menstruation does not return after the climacteric has been established, and that bleeding after the menopause almost always spells cancer. Another warning regarding the age incidence is in place. While cancer usually occurs in the fourth and fifth decades, the most active carcinomata I have yet seen occurred in two unmarried girls under twenty years of age.

There are, however, many cases of menorrhagia, not metrorrhagia, in women of menopause age, where the bleeding due to a benign fibrosis uteri. Medication, endocrine therapy, and douches will usually be of no avail and here radium, 1200 milligram hours, will result in an almost certain cure. But a diagnostic curettage should always be done before the radium is inserted, the possibility of malignancy being always uppermost in our minds.

Stasis the Destroyer

ALFRED C. JORDAN, C.B.E., M.D., M.R.C.P.
London

Immunity from disease depends on the strength of the defences.

While acute disease is not altogether preventable, chronic disease is on a different footing. A community remains free from chronic disease as long as it lives in accordance with Nature's laws of health (1). This important fact seems obvious, and yet is not taken into account by the authorities to whom students of medicine look for guidance.

People who live under unhygienic conditions fall victims to chronic disease (2). Why? Because their tissues become unhealthy and lose their power of resisting the attacks of microbes.

The most widespread and disastrous weakener of the tissues is toxemia. From a septic focus microbic toxins are poured into the general circulation. The focus may be in the teeth, the tonsils, the gallbladder or the appendix, to name only a few. The commonest and most universal focus of all is in the intestines. Since the tissues are supplied with toxic blood they lose their power of resistance and become vulnerable to attack. Any tissue may be attacked and fall a prey to chronic disease. For instance a chronic gastric ulcer never grows in the stomach of a healthy person. Those unfamiliar with this point of view demand proof; it is all too readily available. Take a case of gastric ulcer:

1. The general appearances are not those of health. The complexion is dirty; the skin dry and scaly, stained and inelastic; the hands cold; the ears red.

2. The history reveals evidence of longstanding stasis. Constipation since infancy with perhaps a more recent transit on to mucous diarrhea. Socalled bilious attacks since childhood.

3. The physical examination discloses evidences of stasis: Thickened portions of the bowel can be felt; the iliac colon nearly always; the terminal ileum in many cases. In many instances the ascending colon can be traced downward over the pelvic brim, indicating ptosis of the cecum.

4. The symptoms, though masked now by the severe pain of the ulcer, can be recognized as those of stasis. They are: Headache, backache, muscular pains, aching joints, neuralgia or neuritis, mental depression, loss of memory and many others.

All the physical signs of stasis are confirmed, and many additional details gleaned, by x ray investigation with bismuth (3).

THE FARREACHING EVILS OF STASIS

Some critics raise the objection that stasis is made responsible for almost every disorder known to man. Let these critics consider what "stasis" means. It means not merely stagnation of the intestinal contents, but their putrefaction and the consequent fouling of the blood and lymph streams by the poisonous products of bacterial action. How can any tissue remain healthy under such conditions? Not a single cell can remain normal, for every cell is dependent for its health on the blood and lymph supply. Clearly it is impossible to overstate the evil consequences of stasis.

Other critics argue that the mere discovery by x rays of stasis does not prove that the disease (say gastric ulcer) is caused by stasis. True enough; but that is not a complete statement of the case. A patient is not merely afflicted with a chronic ailment (e. g., asthma, rheumatoid arthritis and duodenal ulcer) but he shows the other physical signs which make up the picture or syndrome of stasis. Further, the efficient treatment of his stasis (whether surgical or medical) not only causes the disappearance of the chronic ailment, but it abolishes all the manifestations of stasis.

CASES

All the following cases had been under medical care yet no progress had been made till the "static" nature of the ailment was disclosed and appropriate treatment adopted. Then followed improvement so rapid and consistent that there could be no doubting the connection. The cases had been labelled—as usual—by the name of the most obvious end result. This label, though appropriate to the case, pointed to a particular symptom so that treatment had been directed to the relief of this symptom but no account had been taken of the general disorder. The best result to be expected from such partial treatment is a temporary amelioration of a particular manifestation of stasis, but no improvement in the general toxemic state. Such a patient is likely to prove a source of continual anxiety, for as soon as he is relieved of his asthma (say), he falls a victim to rheumatism, neuritis, colitis, appendicitis or duodenal ulcer.

SYNOVITIS

CASE I.—The patient was a male, aged eighteen. The case was labelled "Synovitis of the knee." Since the age of twelve the patient had had attacks of "seediness" lasting one week, with diarrhea, frontal headache, and slight fever (100°) and attacks of sore throat often. At the age of fifteen tonsillectomy had been performed but the sore throats still recurred and colds in the head lasting one month. The patient's complexion was pale and earthy, his tongue was coated, and he had a bad taste in the mouth. He had never considered himself constipated as he usually passed a motion daily before breakfast.

An x ray investigation with bismuth was made. The report was as follows:

Elongated pelvic colon, dropped transverse colon, mobile cecum which dropped into the pelvis in the upright posture, elongation and dilatation of the appendix (this organ was habitually in the pelvis with the ptosed cecum), hypertrophy of the terminal coil of the ileum with torsion of its termination caused by axial rotation of the ptosed cecum, spasm of the large intestine (colitis), distention of the gallbladder and tight pyloric spasm causing twenty hours' retention of bismuth in the stomach.

Full "stasis" treatment was carried out. A Curtis belt was worn, paraffin and colloidal kaolin with saline (Kaylene Saline) administered, belladonna given in an alkaline mixture to overcome spasm, a vaccine from the intestinal flora injected, suitable diet and régime imposed.

The synovitis cleared up within a fortnight. There was an immediate gain in weight, strength and stamina. The patient had a successful university career and took part in every outdoor pursuit. His growth and development, which had been "hanging fire," became strikingly active.

Clearly the synovitis—which came on not as the result of any violence to the knee—was but one manifestation of a general toxemia.

TUBERCULOSIS

Case II.—The patient was a girl of sixteen (the daughter of a medical man) with a socalled white swelling of the knee, diagnosed by her father as tuberculous. Dr. A. White Robertson, judging by the toxic appearance of the girl and the physical signs of stasis, suspected the intestines as the source of her toxemia. The laboratory investigations of her urine and feces fully confirmed his suspicions and, to clinch the matter, her knee cleared up rapidly as the result of an autogenous vaccine which he prepared from her intestinal flora.

This case is most illuminating. Clinically the knee was a tuberculous one. Is it possible to decide whether a knee is tuberculous or not? My reply—a somewhat evasive one—is that it is not possible clinically, though quite easy pathologically. The important point, however, is this. No "white swelling" is tuberculous at first; it is micrococcal. The tubercle bacillus gets in later after the tissues have been devitalized by the micrococcal invasion, but the precise moment of the change cannot be detected clinically. The same is true of the lungs.

My x ray experience and observations convince me that pulmonary tuberculosis is not a primary disease. The earliest pathological change in the lung is a micrococcal invasion of the peribronchial tissues weakened by toxemia (4). Thus, intestinal stasis is the primary cause of pulmonary tuberculosis. Stasis causes toxemia; the lung tissues deteriorate, lose their resisting power, are attacked by the micrococci always lurking in the air passages; chronic peribronchial catarrh is set up; tubercle bacilli can now gain a footing, and behold: one more case of "consumption."

The successful treatment of early consumption depends upon the recognition of its toxemic origin. It is not enough to recommend pure air and sunshine, but the tissues must be rendered healthy by measures for correcting stasis.

ASTHMA

Case III.—Labelled "asthma." The patient was a male, aged seventeen and a half years. He had had bilious attacks since babyhood, with pain in the umbilical region. At seven attacks of asthma began to follow some of the bilious attacks. The asthma was relieved or aborted by a dose of calomel. Dr. M. W. Baker, noting evident signs of toxemia, sent the boy for x ray investigation.

I found the appendix tethered so that it caused a block at the end of the ileum, and obstruction was increased by a tight spasm at the ileocecal entrance. The terminal coil of the ileum was distended, the lower ileal coils overloaded. A barium enema showed that the ileocecal valve was incompetent, the cecum habitually overdistended, the duodenum elongated. At operation the x ray findings were completely confirmed. The appendix was removed and the ileum set free.

The success of the treatment was dramatic. There was no recurrence of asthma—that alone was highly gratifying—and there was a striking improvement in health which has remained excellent for the last three years.

Case IV.—This is a parallel case. The patient was a boy aged seven. Nocturnal attacks of socalled asthma started at the age of six. He had been somewhat lacking in energy though otherwise apparently healthy.

On the assumption that the asthma was toxemic, stasis treatment was instituted, consisting of colloidal kaolin (Kaylene), liquid paraffin, belladonna and suitable diet. The asthma was checked at once and never recurred. The general health improved, the complexion became clear, the mind more alert, the body robust and plump. Now at twelve his health is excellent.

PARALYSIS AGITANS

Case V.—Under the heading of "paralysis agitans," a man of sixty-two placed himself under the care of Dr. S. Henning Belfrage. At fifty-seven he had an attack of socalled ptomaine poisoning with vomiting, diarrhea and fever. Nerve exhaustion followed, and no recovery occurred. The chief symptoms were lack of mental concentration, shakiness of hands and arms, every movement took longer than formerly, e. g., adjusting his collar; mental operations took longer and he was unable to do two things at once, e. g., blow his nose while walking. The complexion was very muddy, the tongue coated and flabby. His previous history was interesting: Constipation since childhood, bilious attacks since adolescence—a dose of calomel gave relief—foul tongue, poor appetite, cold hands. At fifty an operation for enlarged prostate, and at fifty-four an operation for papilloma of the bladder.

The x ray investigation revealed a greatly elongated pelvic colon, a firm kink of the iliac colon binding the bowel down in the left iliac fossa, a tortuous descending colon, a dilated cecum and ascending colon, catarrh of the large intestine (colitic), bands at the end of the ileum anchoring the appendix and causing ileal stasis, pyloric spasm.

Sir Arbuthnot Lane operated. He divided the kink of the iliac colon, removed the appendix and set the ileum free. The last twelve inches of the ileum were very thick walled. Improvement set in at once. Before the wound was healed the complexion had improved and the mind had cleared up "as though a veil had been lifted"; the eyes acquired an alert look in place of their former sleepy appearance; his whole aspect and outlook changed from gloom to brightness; last but not least the paralysis agitans had been cured. The improvement was maintained when ordinary life was resumed. It has lasted eighteen months and has every appearance of permanency.

RAYNAUD'S DISEASE

Case VI.—The patient was a female, aged forty; a typical case of Raynaud's disease, under the care of Dr. Ernest W. Martin. There had been lifelong constipation, and since adult life indigestion, pain, distention and flatulence.

My x ray investigation revealed pronounced evidences of longstanding stasis: Dropping and elongation of the large intestine, a kink of the iliac colon, distention of the cecum, severe catarrh of the large intestine (colitis), catarrh of the appendix, an ileal kink, duodenal distention and pyloric spasm with many hours' delay in the stomach.

Mr. Scott Gillett operated, freed the iliac colon, removed the appendix. Three months after operation the last suspicion of Raynaud's disease had disappeared. The hands were warm and of good color; the patient lived an active life, continued on appropriate diet and régime, and twelve months later the improvement was fully maintained.

BRONCHIAL CATARRH

I have records of numerous cases showing such results as these, but must content myself with one more.

Case VII.—The patient was a girl, aged seven. Bronchial catarrh was her most distressing symptom. The child had always been ailing; she had seen eminent authorities, but had received only palliative treatment for the bronchial catarrh. Then pain had occurred in the right iliac region and a surgeon had removed her appendix—necessary no doubt, but not effectual in curing the catarrh or improving the general health.

Dr. A. Graham-Stewart recognized the pronounced evidences of chronic intestinal stasis—the emaciation, the flat chest, the pot belly and the round shoulders; lateral curvature of the spine, the elbows and fingers overextensible, the skin of the face, back, abdomen and axillæ stained, the face pale, apart from the stained areas. The feces could only be described as a "filthy mess," grossly offensive.

My x ray examination revealed ample evidence of severe stasis. The pelvic colon was much elongated, there was catarrh of the mucous membrane of the large intestine; the cecum was distended and mobile; in the upright posture it dropped into the pelvis and turned on its axis causing torsion of the end of the ileum. There was spasm of the pyloric portion of the stomach due to congestion, and such tight pyloric spasm that the gastric contents were imprisoned many hours.

These findings confirmed the clinical signs so completely that Dr. Graham-Stewart commenced "stasis" treatment at once. The response was immediate. At the end of three months the improvement was so great that her father—who had not seen her in the meantime—could scarcely recognize her as his own child. She had gained a stone in weight (four stone to five stone), she was plump and healthy looking, her face was of good color, her skin soft and smooth, *not* stained. There were no long hairs on the back or limbs—they had been shed. The joints were much firmer and less overextensible. The spine was straight.

The treatment that had effected the "miracle" was as follows:

A. Medicinal: Kaylene saline (5) (colloidal kaolin with saline aperient), liquid paraffin, belladonna in an alkaline mixture.

B. Mechanical: A Curtis belt; daily general massage and exercises; rest in bed one hour before and one hour after lunch; fourteen hours in bed at night. Douches of normal saline to wash out the large intestine three times a week.

C. Diet: whole meal bread; fresh fish, fresh dairy produce: milk, cream, butter, eggs; fresh greens, lettuce, mustard and cress, etc.

D. Régime: Fresh air and sunshine: As much of the day as possible was spent out of doors.

THE TREATMENT OF STASIS

Dr. Graham-Stewart's case (just described) may be taken as a model for the principles of treatment. A complete diagnosis is essential. Only an x ray examination with bismuth can determine the exact position of the viscera, the length of the pelvic colon and the existence of kinks and spasms.

Where there is a kink producing constant tight spasm, it must be freed by surgery before other treatment can succeed. When there is an abnormality such as an elongated pelvic colon, the patient must continue treatment throughout life, or the symptoms will surely return. The best drugs for continued use are those which act in the digestive tract and are not absorbed. Liquid paraffin is one of these; another is colloidal kaolin which I introduced recently (5).

Ordinary purgatives are unsuitable for continued use, since they irritate the mucous membrane, and do harm in the long run. Intestinal antiseptics are not as desirable as some believe, for if effectual they kill not only the pathological microbes but also those necessary for the proper functioning of the large intestine. The Curtis belt must be worn if the viscera are ptosed, but the belt must not be permitted to perform the entire function of the abdominal muscles. Although the Curtis belt must be worn the patient must not be allowed to discontinue abdominal exercises. The patient must acquire the habit of retracting his abdomen from the belt. At first this requires a conscious effort but after a week or two it becomes a habit. In the convalescent stage much benefit is derived from appropriate exercises such as the admirable system devised by Mr. F. A. Hornibrook (6). These exercises are designed to strengthen and tone up all the abdominal muscles.

In regard to diet the nonmedical public can find trustworthy guidance in Dr. Leonard Williams's book (7)also Plimmer's pamphlet on vitamines (8).

DANGERS OF TOXEMIA

It is distressing to realize the extent to which civilized nations have become a prey to chronic disease consequent on toxemia. It is an insidious danger making steady inroads into health and stamina. But gradual though the deterioration of tissues may seem, disaster may be close at hand—disaster shattering in its tragic suddenness. A flaming appendix, a perforated duodenal ulcer or gallbladder, retrobulbar ocular neuritis leading to complete or partial blindness and cancer (9)—these are but a few of the innumerable calamities that lie in wait for the toxemic.

Encephalitis Lethargica

W. M. CROFTON, B.A., M.D.
Dublin, Ireland

Encephalitis lethargica receives its name from its most striking and general symptom but its chief symptom may be just the opposite to sleepiness, viz., sleeplessness. Indeed, its manifestations are protean, depending on the position, the extent and the severity of the lesions in the central nervous system. The symptoms may vary from the slightest indication of a central irritation, such as a persistent hiccough, to those of an acute meningoencephalitis with retracted head and death within a few days, or even hours, lumbar puncture giving a clear fluid. If the lesion is in the region of vital centres in the medulla, death may be so rapid as almost to simulate one due to apoplexy. The lesions may be confined to the anterior cerebral hemispheres, the only symptoms being mental. The symptoms may come on during, or immediately after or some time after an attack of influenza; but although this relationship is of extreme significance the infecting agent may not attack sufficient tissues to produce any such generalized symptoms. It would be impossible in the time at my disposal to recapitulate all the symptom complexes that have arisen; suffice it to say, that in any case of queer central nervous complex of symptoms this infection should be thought of and the diagnostic method I suggest below tried.

The deathrate varies in different outbreaks from twenty per cent. to over seventy per cent. of cases attacked. The symptoms may entirely clear up or so many brain cells may be destroyed that the unfortunate patient may have to live his pitiable life in a state of helpless palsy.

PATHOLOGY

There is nothing typical about the pathological changes. The infection appears to be carried by the blood stream, for the walls of the vessels seem to be the first attacked, producing lesions which may be so destructive as to be followed by hemorrhages not only from capillaries but from arterioles and venules. Where the infection is less potent, the perivascular lymphatic is infiltrated with small mononuclear cells, the nerve tissue in the neighborhood being edematous, and the nerve cells are seen undergoing degeneration.

Where the inflammation is more acute, the nerve tissue is infiltrated with red corpuscles, polynuclear leucocytes, and mecrophages, some of the latter at least being derived from the endothelial cells. Polynuclear leucocytes may be seen embedded in the degenerating nerve cells. Some of these da Fano describes as containing minute bodies, which, he thinks, may be the cause of the disease.

If the patient survives and his immunizing response is sufficient, the whole condition may resolve leaving no disability, or the destroyed portion is replaced by sclerosis producing permanent disease. In the acute fulminating cases, the condition may exactly simulate meningococcus meningitis with pus in the cerebrospinal fluid. Such a case was the first I saw of the influenza epidemic in May, 1918, in a boy of five years dying in a few days. The influenza bacillus was isolated in pure culture from the purulent fluid. More commonly there are the symptoms of meningitis, some stiffness of the neck and so on, with symptoms of lethargy, and a clear cerebrospinal fluid sometimes containing more lymphocytes and glucose than normal, sometimes not. In some of these cases the lumbar puncture does not indicate increase of cerebrospinal fluid around the cord, but at postmortem there is marked increase of it in the meninges and cisternæ.

It must be remembered that such brain lesions can be produced by many microorganisms and that because animals have been given encephalitis with these it does not rule out the influenza bacillus. Streptococci capable of producing poliomyelitis, if introduced under the meninges, must be as common as possible in our chronically infected mucous membranes.

ETIOLOGY AND BACTERIOLOGY

The state of opinion as to the etiology of the disease is hopelessly confused, authority asserting that nothing whatever is known of the cause except that the disease has been conveyed to animals by material which has been passed through a filter. This suggests to most minds that its origin is beyond our present means of investigation.

It is, however, the opinion of some epidemiologists that there is a distinct relationship between the pandemics and epidemics of influenza and encephalitis lethargica. I believe Sydenham realized this connec-

tion. Some of those who acknowledge this assert that the infecting agent of encephalitis may give the symptoms of influenza, and that two separate diseases may be confused, since in an epidemic of influenza the symptoms may be nervous, the onus falling on the central nervous system instead of on the respiratory or the digestive system. It appears to me, however, that the epidemiological relationship is too significant to be ignored.

But, if this is so, what is the cause of influenza? Again, authority seems to be of the opinion that it is due to a mysterious filter passer. When confronted with the fact that, when proper means are taken, the Pfeiffer bacillus can be isolated from the vast majority of cases, the answer is that this was not so during the original pandemic but only occurred later on in succeeding epidemics; that Pfeiffer himself could only isolate it in fifteen per cent. of cases. This latter fact is quite true, as ordinary blood smeared agar medium or other unsuitable medium was used, and no precaution taken to prevent material getting cold between the patient and the incubator. But it is quite untrue to say that the influenza bacillus could not be isolated from practically one hundred per cent. of the cases in the original pandemic. Those of us who used a proper medium, such as agar containing ten per cent. of unheated blood, at body temperature at the time of insemination and kept warm on its way to the incubator, did isolate the bacillus in over ninety-five per cent. of all cases in the acute stages during the original pandemic. Moreover, with a pure antigen of the bacillus we, in the very midst of the pandemic when in University College, where most individuals were infected, produced protection in over eighty per cent. of the cases. Such a pure antigen rapidly aborted the disease and, if given in sufficient dose, would produce transient symptoms of the disease.

To my mind such evidence was and is sufficiently conclusive. How conclusive such evidence of pathogenicity is, I was able to show in the case of such a fatal disease as diphtheria in fowl, from which I isolate a microbe morphologocally and culturally similar to the influenza bacillus. Since, with a pure antigen of this microbe, I was able to prevent and cure, during the epidemic of diphtheritic roup (that is, significantly to reduce the morbidity and mortality), I knew I was dealing with the cause. The final proof was open to me in this case, and I was able to reproduce the disease in hens from an uninfected source with the microbe.

How then are we to account for the symptoms of influenza and encephalitis being transferred to animals by material passed through filters, and such experiments as McIntosh and Fildes who produced encephalitis in animals with filtered material from the brain of a patient dead from influenza, even when the brain had been preserved in glycerine, a significant experiment if I establish my contention as to the cause of encephalitis (for a microscopic microbe must be looked for in such diseases as smallpox and rabies).

Microbes are no exception to the biological law that morphology is influenced by environment. In the case of microorganisms, generations succeed each other so rapidly that change of morphology is very easy to demonstrate. They have exceptional capacity to adapt themselves to an inimical environment, some individuals being able to produce ferments capable of digesting the environment in which they are and transmitting this capacity. This adaptation and subsequent multiplication accounts for the incubation period after infection. Microbes are strikingly pleomorphic. As some of you may remember, I demonstrated the pleomorphism of Kedrowski's leprosy bacillus, many years ago, at the section of pathology and bacteriology, showing it as a coccus, a short bacillus, a diphtheroid, a streptothrix, all of these both acidfast and nonacidfast.

When first isolated the influenza bacillus is most minute requiring the highest power eyepiece for its identification. As it adapts itself to a saprophytic existence, by culture, it gets much larger, very long forms appearing, quite unrecognizable as the influenza bacillus if we did not know their derivation. I am not at all sure that in some carriers it does not exist in such an enlarged form and therefore is not recognized.

There are two ways in which a microbe may become small enough to pass through a filter, if indeed they are essentially different; that is, by splitting into two the product remaining small, or by breaking up into splitta corresponding to the infective granules of protozoa, and familiar to everyone in the case of the tubercle bacillus as Much's granules. It is possible that such splitta are resistant under inimical circumstances, such as cold, starvation, or immersion in glycerine, and in the case of such a delicate organism as the influenza bacillus, which must in ordinary circumstances be transferred from warm mucous membrane to warm mucous membrane if infection is to be transmitted enabling it to survive. In the body itself, an infecting microbe may be present doing its destructive work in a particular region, and yet it is quite impossible to demonstrate it in section or smear. The pus of a tuberculous abscess is a well known example; and yet, when such material is injected into a susceptible animal, infection is certain. From material infected with other microbes, a profuse growth may be obtained on culture media in which no microbes could be identified in smear or section. In the tissues the microbes are growing in a reduced oxygen tension; a potent way of altering the morphology of some microbes in the testtube. It is quite possible, however, that under some circumstances the microbe is seen in the tissues and not recognized owing to its changed appearance. I think it quite possible, for instance, that the minute intracellular inclusions demonstrated by da Fano in the brains of patients dead from encephalitis lethargica are the infecting influenza bacilli.

It appears to be generally accepted by authority that microbes which pass through a filter belong to a special class of pigmy microbes that never get bigger if their environment is changed. This is not so in the case of the class of microbe we are considering. There may be such uniform pathogenic microbes of course. Let me give an example of the passage by N. S. Ferry of a minute bacillus, no smaller, however, than the influenza bacillus, the Bacillus bronchisepticus described as the cause of canine distemper, a hardy bacillus which will grow on all ordinary media. It varies in size from 0.5ux0.5u (that is a minute coccus) to 2.3ux0.5u

(that is a minute bacillus). Ferry took a dozen candles each of Berkefeld V, Berkefeld N and Chamberland F candles and very carefully tested them by air pressure under water. Of the thirty-six he found that all but seven failed to satisfy the high standard of efficiency he set. The microbe was grown both in broth and on agar, the broth was filtered direct, the agar culture suspended to about the same density as the broth culture. The pressures used were gravity, fifteen pounds negative and 225 pounds positive. The results of the work proved conclusively, according to all the rules laid down for filterable viruses, that the Bacillus bronchisepticus is a filterable virus

Now Carré has demonstrated, and it is generally accepted, that the cause of canine distemper is a filterable virus, and that the work of Ferry, McGowan and Torrey describing the Bacillus bronchisepticus as the cause is therefore wrong, and the same holds good for hog cholera. This latter case has been held up to me as showing that I was wrong in asserting that the influenza bacillus was the cause of influenza, since the discovery of a filter passer in the case of influenza entirely ruled out the influenza bacillus as anything but a secondary infection, as it did in the case of hog cholera. Rosenow has shown that the streptococcus of anterior poliomyelitis can pass through a filter and the Leytons that a streptothrix in its minute stages can do so too. Moreover, it is generally considered that if an organism can pass through a filter, it is invisible. Nothing of the sort! Many of the filter passers can be demonstrated in their minute forms microscopically. The passage through a filter, therefore, does not rule out a microscopic microbe as the cause of a disease. I have always asserted this in the case of the influenza bacillus.

SUMMARY

1. Influenza is caused by the influenza bacillus, and this fact was established when a pure antigen of it prevented and rapidly cured the disease producing general and focal reactions.

2. That such reactions establish pathogenicity, I have shown by a pertinent animal experiment in the case of a similar microbe which I have established as the cause of diphtheria in fowl.

3. The demonstration of a filter passer as the cause of a disease does not rule out any microbe as pathogenic, as there may be a minute form of it capable of passing through a filter.

Similar evidence identifying the influenza bacillus as the cause of encephalitis lethargica is available. It is a local manifestation of an infection with the influenza bacillus, for a pure antigen of the influenza bacillus produces general and focal reactions and cure—that is, provided it is used before so many nerve cells are destroyed that recovery is impossible. The etiological conclusions come to from this evidence has been confirmed by the isolation of the influenza bacillus from the blood of eight out of eleven cases of encephalitis lethargica during the acute stages, by Dr. M. Enright, assistant to the professor of pathology, University College, Cork. Is it likely that microbes so isolated were secondary infections?

DIAGNOSIS AND TREATMENT

When the meningeal symptoms are predominant the diagnosis lies between meningitis due to pyogenic organisms, influenzal meningitis and tuberculous meningitis. A lumbar puncture with culture distinguishes between the first two, as the production of pus in the cerebrospinal fluid by the influenza bacillus is rare but always must be remembered. If the fluid is nonpurulent there is much more difficulty, as the only point between the fluid in cases of tuberculosis and in some cases of encephalitis lethargica is an increase of copper reducing substance in that of encephalitis.

If the meningitis be accompanied by lethargic symptoms, or if the lethargica symptoms predominate or are present alone, the clinical diagnosis is simplified, as it is if the brain symptoms occur in an ordinary attack of influenza. The same difficulty arises in the chronic cases with localized lesions such as incoordination pointing to a cerebellar lesion or such like—a history of a previous attack of influenza being suggestive. All these uncertainties can be easily cleared up if a potent antigen of the influenza bacillus is available. In the acute cases the result of giving a one million dose is frequently remarkable. I have had a profoundly lethargic patient sitting up talking sensibly in two hours after such a dose, another in six. Sometimes there is a negative phase with increased symptoms which, with involvement of the meninges, may necessitate lumbar puncture to relieve pressure, just as a similar reaction does in the active immunization of meningococcus or other suppurative meningitis. The series of one, two, three, four million may be given, the intervals being dictated by reaction. As a rule, these doses are all that is necessary in the acute cases. If the case has lasted longer before treatment has commenced, the doses must be increased until the desired result has been obtained; it is rarely necessary to go further than twenty million. So responsive are patients with lethargy to this antigen that they furnish a test for it, so that, if they do not respond, it is because the antigen is impotent. A small but typical series treated in this way is described in the *British Medical Journal* (March 27, 1920). Many others since then have obtained similar successful results. Let me give a few typical cases:

Case I.—A medical student had had for some days a temperature ranging from 100° to 102° before taking to his bed. He complained of seeing double. He became increasingly sleepy, was delirious, and had hallucinations; when spoken to he could be roused up, and talk fairly sensibly. His conjunctivæ were congested, he was badly constipated, and passed urine under him. He had, in fact, symptoms suggestive of lethargic encephalitis. On the chance that the infection might be caused by the influenza bacillus (the case occurring during the epidemic) I gave him subcutaneously two and a half million pure influenza antigen. The improvement was marked at the end of twelve hours. Thirty-six hours later I gave him five million, and forty-eight hours later seven and a half million. After this he had complete control of his functions and he was no longer lethargic, although his memory was still defective. He still had difficulty in reading, and his temperature was not quite normal—99° F. I then gave him ten million in the morning, forty-eight hours after the last dose: that evening his lethargic symptoms returned in full intensity, although there was no further rise in tem-

perature. His mind did not become normal again for two days. He made a rapid convalescence, but could not read for any length of time or study for some months. The focal reaction after the last dose makes it to my mind, certain that the influenza bacillus was infecting his brain.

Case II.—An elderly gentleman when first seen by me had been ill for a week with lethargy and bronchopneumonia. Micrococcus flavus, streptococci, and influenza bacilli were isolated from his sputum. He was exceedingly ill. The temperature was 102°, the pulse 90 to 100. He was given at once a mixed antigen containing the above microbes pending the making of an autogenous antigen. The first dose was one and a quarter million of each. There was a distinct improvement in twenty-four hours. Forty-eight hours after the first dose he was given two and a half million of each. The next dose of his own antigens contained the same amount and was given at a similar interval. The doses were continued up to twenty million of each. All his symptoms and physical signs rapidly cleared up so that at the end of ten days he was convalescent. He had no recognizable reactions after any dose, and made an uninterrupted recovery.

Case III.—A woman, aged twenty-two, became ill on December 25, 1919. She felt exhausted and sleepy, and in her sleep talked continuously, was very restless, and had jerking movements of the limbs. She had been overworking, and had had two falls the week previously; she had had a nervous breakdown at the age of sixteen, when she suffered from undue sleepiness; for some time I thought her symptoms could be similarly accounted for. When wakened from sleep she roused with a start, and told me she was very well; after a few minutes her eyes became fixed, the eyelids closed, and she was asleep again, resuming the muttering and restless movements. She roused occasionally, and took food well. She was constipated, but got out of bed to urinate. At first she used to get up to sit by the fire, but always went to sleep in her chair.

After a time, since the sleepiness was getting worse rather than better and her memory for my previous day's visit was a complete blank, I determined to give her a dose of two and a half million pure influenza antigen. It was given at 10:30 a. m. on January 13th. She was asleep within five minutes of getting it. Two hours after she woke up excited, nervous, and shivering, and was given ten grams of aspirin. The unpleasant symptoms passed off in an hour or two, and that evening she was much better, and able to talk rationally, and had no symptoms of lethargy. She slept much more normally that night and was much less restless during her sleep.

When I saw her next morning she laughed and talked to me quite naturally. She improved steadily for some days, then began to get sleepy again and the other symptoms returned. On January 20th I gave her two and a half million, and she had the same symptoms as before but to a less extent, and next day was awake smiling and talking to me normally. Three days later, on January 23rd, I gave her three and three quarter million; she went to sleep after it, and remained lethargic that and the whole of the next day, being roused up to take her food and then going to sleep again. Forty-eight hours after she was herself again. Since then she has been given five million on February 2nd and five million on February 13th; this dose was delayed by three rather severe attacks of palpitation and then an attack of colitis. On February 16th she was given seven and a half million and on February 20th ten million. On February 23rd she was quite convalescent. I have continued her doses up to twenty million so as to leave a margin of safety. The temperature was normal throughout.

Case IV.—The patient, a girl aged five years, living in the South of Ireland, was taken ill on February 18, 1921, with shivering, drowsiness and headache most intense behind her eyes. She was seen (by D. C.) on February 21st, when her temperature was 102.6° F., the pulse 120. She was asleep, and could only be roused with difficulty; when the eyes were open the conjunctivæ were seen to be injected—the typical pink eye of influenza. She was very constipated, necessitating enemas, but she had not incontinence of urine. There was a watery discharge from the nose. She had muscle twitchings—marked in the eyelids. When roused she answered questions slowly but intelligently, but was profoundly asleep again within a few minutes. Her temperature fell to 99° and her pulse to 95° by February 24th, but the lethargy seemed to increase, the patient only being awake when roused to take food. W. M. C. was then consulted, and one and a quarter million Bacillus influenza antigen were given on the morning of March 2nd under the skin of the hip; her temperature was then 99° and the pulse 95. She was asleep again a short time after the injection. At the end of six hours she woke up quite bright and cheerful; the temperature had fallen to 97.4° and the pulse to 76. She remained awake for four hours. On March 4th she remained awake from 9 a. m. to 6 p. m.. The drowsiness then gradually increased again until, on March 10th, she was given two and a half million. She slept for three hours and woke up bright and gay. Next day (March 11th), a reaction appeared. She slept a good deal. She complained of headache. The temperature rose to 99.4° F., the pulse to 115. The discharge from the nose came on again, and the conjunctivæ were injected. These symptoms had passed away by the next day, and she has remained normal in every way since. She was given a few more increasing doses of antigen.

Case V.—Mrs. X., an elderly lady whom I had previously treated successfully for sprue, was taken ill on a Saturday evening with a slight rigor. Next day she had fever, vomiting, and diarrhea, and later that night severe headache, retraction of the head, Babinski and other signs of meningitis. When I saw her next morning, in consultation, there was less rigidity of the neck, and I thought typical symptoms of encephalitis lethargica. I gave her a dose of antigen containing one and a quarter million influenza. That afternoon the meningeal symptoms increased and a lumbar puncture was done, clear fluid being withdrawn. Next morning she had regained consciousness and the meningeal symptoms had almost disappeared. She made an uninterrupted recovery without further specific treatment.

The treatment of palsied cases is, of course, most

unsatisfactory. Large numbers of nerve cells have been destroyed and cannot be replaced. Cases treated by a proper antigen do not get palsy, just as cases of influenza treated at once with a proper influenza antigen do not get pneumonia. It is, however, always worth while trying, and I have seen such cases get sufficient relief as to be able to return to work, but very many of them remain crippled. In the treatment of such cases there is always the possibility of a secondary infection, so that it is well to make a bacteriological examination of the urine and include the antigens of any microbe found. Finally, if the influenza bacillus is not the cause of encephalitis lethargica it is an exceedingly fortunate thing that it furnishes such a potent method of treatment. To me the evidence is conclusive that it is.

Medicolegal and Sociological Aspects of Epidemic Encephalitis*

CHARLES S. POTTS, M.D.
Philadelphia

While epidemic encephalitis first appeared in this country in 1918, it was not until several years later than the seriousness and frequency of its sequelæ began to be realized. Thus, at the meeting of the Association for Research in Nervous and Mental Diseases in December, 1920 (1), when this disease was investigated, little time was devoted to this phase of the subject. They were mentioned as occurring but the impression conveyed was that they were frequently recovered from. Since this time considerable has been learned that was not known then. The literature for the past two or three years has contained a large number of papers devoted to a consideration of both permanent symptoms that followed directly the acute attack and of those which developed some time later. No one, so far as I know, has specifically called attention to the aspects embodied in the title of this paper. To be sure, those who are thrown into contact with considerable numbers of these cases recognize their importance. Those whose work is not along neurological and psychiatrical lines do not.

Both mental and physical states occur which may bring the patient either into conflict with the law or cause him to become a public charge. Before discussing these, it seems of some importance to call attention to a peculiarity of the lethargy or stupor which so frequently is a symptom. This is, that while apparently in a stupor, they can be easily aroused, and when aroused often show alertness and mental clearness. Hohman (2) says "The clearness and alertness on being aroused is surprising; one would not expect as much wideawakeness in a normal person aroused from sleep." I have seen a patient awake from a lethargic state and correct a mistake in an arithmetical calculation that was made during a conversation held in her presence. While in this state they not infrequently remember statements made by others in the room. Another peculiar feature is that periods of delirium, stupor and mental clearness may alternate. Kirby and Davis (3) mention a patient who stated that "I was out of my head at night but sensible during the day." The question might arise, Is such a patient competent to make a will? Some, no doubt, are. Every case, however, must be decided on its merits as on the other hand many are incapable of sustained or logical mental effort.

The sequelæ may be divided into three classes: 1, Those which follow directly a well marked and recognized acute attack of the disease; 2, those which follow an unrecognized acute attack; 3, those which do not develop until some time after the attack. The first class as a rule do not cause errors in diagnosis; the other two do and it is to these that I wish to call attention.

It is of the greatest importance to bear in mind that subacute cases occur (4), in which the onset is insidious, the symptoms those of a mild influenza type for which the patient does not either go to bed or consult a physician. Later on, in some, symptoms of a typical acute attack may develop; in others, after a long period, some of the sequelæ.

It is of equal importance to remember that typical cases apparently cured may develop symptoms after several years. Weinberg (5) says: "It is important to bear in mind that the severity or mildness of the condition during the acute stage has no definite relation to the sequelæ." He mentions a patient who only came to the hospital because of pain in the back which had been erroneously diagnosed nephrolithiasis. Schaller and Oliver (6) report a case persisting for over a year, whose main complaints were abdominal pain and gastric distress, thought to be due to chronic appendicitis. Operation proved the falseness of this diagnosis and autopsy later, the existence of a chronic encephalitis. The first stage of this man's illness was thought to be influenza.

The mental sequelae vary from impairment of memory and disturbances of sleep, the latter often consisting of abnormal drowsiness during the day and insomnia at night, to mental deficiency and insanity. Children are especially prone to develop mental disturbances. These have been summarized by Ebaugh (7) as "Total change in character and disposition, with hyperkinetic states, leading to behavior oddities, consisting of emotional lability, sexual precocity, general incorrigibility and mental deficiency." Leahy and Happ (8) state after studying a large number of children that those patients who apparently had made a complete somatic recovery, not infrequently showed some striking form of abnormal behavior, among which they mention purposeless, impulsive motor acts, marked irritability, definite attention disorders, distractibility, insomnia, sexual precocity, and intense eroticism. It is easy to see how such symptoms may bring these children into conflict with the law and that many of them will be-

*Read by invitation before the Medico-Legal Society of Philadelphia, January 27th, 1925.

come public charges. That many of them, previously honest, develop strong tendencies to steal, and others to commit sexual offences, is important in this connection.

Behavior oddities probably do not develop so often in adults as in children. They do, however, occur. Other mental states which may lead to diagnostic error and injustice are hypomanic states, especially associated with great loquacity; (2) Korsakoff's psychosis, paranoid states, suicidal and homicidal impulses and symptoms resembling those of paresis. As Korsakoff's psychosis is usually due to the excessive use of alcohol, it can readily be seen that jumping at conclusions may lead to a diagnosis which may do great harm to the reputation of the patient and might prevent, for instance, his collection of insurance. House (9) reports a case of a man who a year after the acute attack developed delusions of persecution, with hallucinations of sight and hearing, directed against his wife. He transferred his life insurance to others, changed his will, eventually attempted to kill her and then committed suicide. Paresis may be simulated by both mental and physical symptoms. Kirby and Davis (3) mention a case in which there was an acute onset with insomnia, speech and expression of grandiose trend, as talking of wonderful inventions, etc. As will be detailed later, physical symptoms resembling those of paresis may occur.

Neurasthenic states, long persisting, are not uncommon; for instance, Hess (10) examined seventeen cases from one to two years after apparent recovery. They complained of diminished capacity for work, poor memory, weakened perceptive faculties, lack of will power, energy and change of character. Many such patients are thought to be merely lazy as for example: A young man twenty years old was brought to me by his father, who made the statement that the boy had become lazy and careless about his person and could not be gotten out of bed in the morning. "If I said there was nothing the matter with him, he was going to knock hell out of him." Inquiry elicited that three years previous he had had an attack marked by desire for sleep, "turning in of the eyes and seeing double." He was not, however, confined to bed. The present symptoms had developed since. One year later, or four after the acute attack, tremor of Parkinson's type developed. Morbid impulses and phobias have been reported (11).

An important case illustrating mental sequelae of the type indicated as Class 3 in this paper is reported by Goodhart and Cottrell (12). In brief, a young man of previous irreproachable conduct, several years after what was believed to be a complete recovery from encephalitis, developed marked sexual aberrations. Otherwise mentally he was normal and his behavior good. Examination showed some, but not marked, physical signs of the disease.

Physical symptoms that persist, especially if those of the original illness have been mild or have not been noticed, are not infrequently mistaken for either syphilis or hysteria. Those referable to the eyes, especially resemble those of the former. Duncan (13) in a follow-up several years later of 101 cases who had had the disease between March, 1918, and September, 1921, found diplopia in ten unequal pupils in twenty-nine, irregular and eccentric pupils in twenty-eight, defective reaction to light in twenty-one, defective reaction to accommodation and convergence in twenty-nine, typical Argyll-Robertson pupils in two, and ptosis in six. In addition, it might be stated that he found mental symptoms of different degrees in fifty-six. Probably the most serious being three children who stole whenever opportunity offered, although previously they had been honest. Grossman (14) in a series of cases found 30 per cent. had pupillary disturbances. Five of these were of the Argyll-Robertson type; one developed primary optic atrophy. That these symptoms are common to syphilis of the nervous system will at once be recognized. Another important fact is that either a luetic or paretic curve may occur with the colloidal gold test. (15). To be sure, these occurred in acute cases, but again it must be remembered that the acute symptoms in many cases are mild and atypical. Hohman (16) has reported several cases which presented, among others, a peculiar ocular symptom. This was a forced conjugate upward movement of the eyes. This symptom, he states, has been known to ophthalmologists only as a symptom of hysteria. His cases were undoubtedly due to encephalitis. One of the patients had been discharged from his position as a street car conductor on account of it, and one, while she had had previous acute symptoms of the disease, they were so slight that no attention was paid to them at the time. Epileptic convulsions (17) may result and as these in adults are not infrequently the result of syphilis, care must be taken in arriving at an opinion. This is especially so if pupillary symptoms are also present. That a mistaken diagnosis of syphilis may cause great injustice and trouble for a patient in many ways is evident. In this connection it may be stated that many physicians make this diagnosis too lightly and without sufficient evidence.

Various peculiar disturbances of respiration (18) not infrequently result. The usual one is paroxysms of rapid breathing. Somewhat similar symptoms may be due to hysteria. A mistaken diagnosis may be serious. The following brief abstracts of the histories of cases are illustrative of the foregoing.

Case I.—I have recently seen a man who received a blow on the head at his employment. He was able to return to his work and had no trouble for a week. Then he stated that he developed diplopia, which persisted for several days and was alternately stuporous and delirious for a week. He had fever and was confined to bed for three weeks. Two months later he developed spells of rapid breathing, which have been growing worse until the present time. The spells resemble very much the breathing of one who has undergone some great physical exertion. He has been able to work some until a month ago, when he had to cease, and he has applied for compensation. Several physicians who examined him for an insurance company stated that it was hysteria, which it evidently was not.

Case II.—A man, twenty-three years old, presented a typical Parkinsonian syndrome of encephalitis, which he had had in 1921. The interesting point is that the tremor and present disability did not appear until three years later and followed a fall from a bicycle. Since this time also he has been drowsy and unable to work.

Case III.—A man, thirty years old, was well until eighteen months before being seen by me, at which time he was said to have had a nervous breakdown. This was said by his physician to be due to his teeth, a number of which were drawn. Inquiry elicited the facts that he then had tremor, diplopia and pains in the head and shoulders. He has been unable to work but little since and his brother who was with him suggested that he was lazy. Examination showed Argyll-Robertson pupils, tremor of the hands, a peculiar clonic spasm of the masseters, as if he were having a chill, insomnia, etc. No serological evidence of syphilis was present.

Case IV.—A man, twenty years of age, in 1920 had an attack in which he was confused, and hallucinated for several days. He also became jaundiced for which his gallbladder was drained. Several months later he noticed difficulty in walking and he developed the Parkinsonian syndrome. For some time it was noticed that while he could not walk well, he could run and dance. This is a peculiarity which sometimes occurs in these cases and may lead to suspicion that the patient is suffering either from hysteria or simulating.

Case V.—A man, forty-five years old, was well until 1920. He then had encephalitis but apparently recovered and worked as usual for three years. He then developed a Parkinsonian syndrome and is now helpless.

Case VI.—A young man, aged twenty, had encephalitis in February, 1920. He remained well until June, 1923, when he had an epileptiform convulsion. This was followed by the gradual development of the Parkinsonian syndrome.

Case VII.—A man, forty-three years old, had unequal and rigid pupils. This was thought by several physicians to be luetic. Serological tests and history were negative. Inquiry determined that three years previous (1919) he had had diplopia associated with headache, general muscular pains and fever.

The notes of the following cases have been given me by Dr. William Drayton, neurologist to the Municipal Court of Philadelphia. They are only a few of the many such which come under their observation. They are interesting because either the existence of a previous encephalitis was not recognized or the patient was thought to be cured. They were brought to the court as incorrigibles in the case of the children, as derelicts either in supporting their families or in the observation of the ethical requirements of society, in the case of the adults.

Case VIII.—G. T., aged eleven; was in Grade 5B at school before having encephalitis; afterwards she wandered away from home, stayed out all night, went to Chester with a man.

Case IV.—I. M., aged eight—after encephalitis in March, 1923, has been irritable, kicks and bites her mother who cannot control her. Her mentality otherwise is above normal.

Case X.—G. M., aged twelve years—did well in school until 1921, when she had encephalitis; since then she has not advanced, lies, runs with the worst girls she can find and masturbates.

Case XI.—A. P., aged seven—was ill several weeks in February, 1923, during which he slept most of the time. Since then he breaks windows, beats other children, is nervous, and has a violent temper.

Case XII.—V. L., aged eight—had encephalitis in 1921 when he was ill for six weeks. Since then he has set fire to the house three times, stays out late at night, hits other children, urinates and spits on the beds of other people, does not sleep at night and talks to himself. It is interesting that his parents attribute the symptoms to his having been hit by an automobile.

Without proper study such children might be considered as merely bad and not altogether irresponsible especially as some carry out intelligence tests well.

Case XIII.—A. W., aged twenty-five—had an illness in 1918 in which she was drowsy for a long time. This was thought to be influenza. Prior to this she was an inspector in a manufacturing plant and had been four years in one place. Since then she has been continually discharged from her positions, stands about staring into space, and has a violent temper.

Case XIV.—H. W., aged twenty, was normal until 1921, he then had encephalitis, after recovering from which he was dopey, grabbed girls on the street by the legs, for which he has been sent several times to the house of correction. He also masturbates continually.

Case XV.—J. C., aged thirty-seven—was well and normal until 1920. He then had an acute illness, undoubtedly encephalitis, but which was attributed to poison liquor. Since then he has not worked, his temper is violent, he is extremely hypersexual and has threatened to kill his wife for not submitting to his embraces as often as he desires.

It will readily be admitted that many of these cases may come into conflict with criminal law for more or less serious infractions. It will also be admitted that they are irresponsible although some of them, if guilty of homicide, might, by our archaic system in deciding such cases, be adjudged responsible.

Many of them may also have a bearing on civil law, in reference to negligence and compensation.

I have mentioned three cases where the symptoms within a brief period followed trauma (I, II, XII). While it is possible that the disease would have developed anyhow, it must be borne in mind that trauma may excite the symptoms of organic nervous disease, especially in those predisposed. On the other hand it must be remembered that patients frequently attribute their condition to a previous accident although they either may have been present and not noticed or too long a time has elapsed between the trauma and the appearance of the symptoms. A careful history in such cases is imperative.

SUMMARY

Epidemic encephalitis may occur without the classical symptoms of the acute stage and this stage is often unrecognized. Such cases may develop physical and mental symptoms later than simulate those of other nervous diseases. Typical cases apparently cured may develop such symptoms after a varying period of health. The physical symptoms may resemble those caused by syphilis, neurasthenia and hysteria; the mental, especially those due to syphilis, alcohol and other toxemia. Sudden changes in personality and behavior, especially in children, should arouse suspicion as to the possibility of the condition being postencephalitic. In children it must be

remembered that the child may be apparently bright except for its bad behavior. Criminal tendencies may be so caused. The question whether a trauma of the head can predispose to the development of the acute attack and excite the sequelæ in one who has had the disease must be considered. Patients in the stuporous state may hear and remember what is said in their presence and may have periods during which they are mentally alert.

The author's references will appear in his reprints.

Etiology of Epileptiform Convulsions

A Study of Two Hundred and Ten Case Histories

JOHANNES M. NIELSEN, M.D.
Battle Creek, Michigan

A series of 210 consecutive cases of epileptiform convulsions has been analyzed with a view of determining their etiology. This work is based on the following principles:

1. An epileptiform convulsion is a symptom.
2. A convulsion may be a symptom of a functional or organic disease complex, or of the entity called idiopathic epilepsy.
3. There are some pathological conditions which are generally considered capable of producing epileptiform convulsions.
4. Cases in this series may be classified during the study as symptomatic and idiopathic; the symptomatic group (fifty-seven) constituting those in which a recognized cause of convulsions exists and appears to be the only cause; the idiopathic group (153) constituting those in which no adequate cause is found.
5. No work of this kind is of value unless the cases are carefully checked with a nonepileptic series. The nonepileptic series in this paper consists of two hundred consecutive cases in which none of the nervous manifestations which are to be considered as having an hereditary influence on epileptiform convulsions occurred. It will be noted that the diagnoses in the two series were made by the same physicians and under the same conditions. This eliminates largely the personal element and the influence of opinion.

Throughout this paper all doubtful cases have been excluded, and only very definite ones used; e. g., if a patient is "occasionally" constipated or uses cathartics "once in a while," that case is not used in a study of constipation. All doubtful ones are considered unknown.

The cases were studied under the headings of hereditary taint in ancestors (not siblings, since this is not heredity), age, sex, constipation, basal metabolism, blood sugar, blood pressure, hemoglobin, association with migraine, differential blood count and x ray findings. These headings will be taken up in turn. Throughout this paper the symptomatic group consists of the following: Arteriosclerotic, fifteen, increased intracranial pressure, eight, Jacksonian convulsions (exact etiology unknown), eight; toxic, five; hysteria, five; lues of the central nervous system, four; meningitis (nonluetic), two; scar from hemiplegia, two; hemorrhage (subdural), two; hypopituitarism, one; thyroid and ovarian dystrophy, one; encephalitis, one; meningoencephalitis, one; brain tumor, one; pathology after skull fracture, one, a total of fifty-seven. I doubt, however, that many of the socalled causes are alone sufficient to produce convulsions.

Recognized causes of epileptiform convulsions have been gathered from the literature and classified as follows:

General cerebral pathology	*Local cerebral pathology*	*Toxemia*
1. Concussion	1. Abscess	1. Arsenic
2. Encephalitis	2. Arteriosclerosis	2. Carbon Monoxide
3. Idiocy	3. Hemorrhage	3. Diabetes
4. Insolation	4. Hydrocephalus	4. Eclampsia
5. Lues (interstitial)	5. Meningitis	5. Influenza
6. Multiple sclerosis	6. Softening	6. Rabies
7. Myoclonus	7. Traumas	7. Rheumatism
8. Paresis	8. Tumors	8. Strychnine
		9. Syphilis
		10. Thyrotoxicosis
		11. Uremia

Functional	*Endocrine*
1. Compulsion neurosis	1. Hypopituitarism
2. Dementia Precox	2. Thymus diseases and extirpation
3. Hysteria	3. Parathyroid diseases and extirpation

Cardiovascular	*Border Line*	*Experimental*
1. Adams-Stokes syndrome	1. Affect epilepsies of Bratz	1. Cortical stimulation
	2. Migraine	2. Decerebration
	3. Narcolepsy	3. Toxemia
	4. Vagal and vasovagal attacks	

HEREDITARY TAINT

The factors considered influential in heredity are: Insanity, epilepsy, hysteria, psychoneuroses, migraine, alcoholism and socalled extreme nervousness. All such cases have consequently been eliminated in choosing the control series. Whether or not all these could be influential need not be discussed here since the same factors have been considered in the control cases. (Table 1.)

All symptomatic cases in which less than five of a type were known have not been entered as so small a series would be of no value.

Since hereditary taint was present in only 10.5 per cent. of the non-neurotic series and was considerably greater in the others, it is evident that heredity is a factor of importance. The striking fact is that apparently all patients in whom epileptiform convulsions develop regardless of the presence of adequate pathology show a marked hereditary factor.

AGE

In 204 cases the age at the time of the first convulsion was known. These have been grouped into

five year intervals for purposes of study and the curve drawn. (See Fig. 1.) It will be seen that regardless of etiology there are three peaks—at twenty, at thirty to thirty-five, and at fifty. This curve seems extremely difficult to explain. Are we to account for the three peaks, or are we to explain the low points at twenty-five, forty to forty-five, and at the end? Assuming that the first rise is due to the strain of adolescence and the third to degenerative processes of advancing years, an effort has been made to explain the second rise by a study of sex, constipation, basal metabolism, blood pressure and heredity. We find 73.5 per cent. of this group to be with males as compared to 60.2 per cent. in the entire idiopathic series. We find 87.2 per cent. are constipated as compared with 87.2 per cent. constipated in all idiopathic cases and 66.3 per cent. in controls. We find average basal metabolism to be —10.4 as compared with —10 in all idiopathics. Blood pressure average is 115, in all idiopathics 116. Hereditary factor is 32.4 per cent., as compared with 40.6 per cent. in idiopathics. This leaves us with just one factor to explain the rise—male sex. A study of the sex question shows that the male preponderance is partly explained in the symptomatic series by alcoholism, syphilis, and other causes, but the distinct rise in the idiopathic curve between twenty-five and thirty-five is not explained. The very slight influence of arteriosclerosis is shown graphically (dotted line). It is seen to account for a certain small group only and these with one exception after the age of fifty.

SEX

In the idiopathic series 60.2 per cent. were males and 39.8 per cent. females. In the entire series 65.7 per cent. were males and 34.3 per cent. females. This is in fair agreement with figures of others.

CONSTIPATION

The influence of constipation is shown in Table 2. It is very evident that the females preponderate in constipation. Since the males have the preponderance in epilepsy, the question arises whether constipation is of much importance in the etiology of epilepsy. The totals will answer this question. In the symptomatic cases there is an incidence of constipation of twelve per cent. and in the idiopathic cases of twenty-one per cent. greater than in the non-neurotic series. In addition to this, it is well known that acute constipation occurs in an epileptic at the time of an attack.

BASAL METABOLISM (AUB-DUBOIS METHOD)

This had been determined in fourteen cases of the idiopathic series, and in only four of the symptomatic cases. The average for the idiopathics was —10, for the symptomatics —8.5, while the average normal by this method is about —4. There is apparently a slight but definite decrease in basal metabolism in cases of epileptiform convulsions, but the series is too small to do more than suggest.

BLOOD SUGAR

The blood sugar had been determined in fifty-four cases of so-called idiopathic epilepsy and the average was 97 mg. per one hundred c.c. of blood. The normal varies from 90 to 110.

BLOOD PRESSURE

To facilitate the study of blood pressure as a factor, Table 3 has been prepared. A study of the table reveals that while the average blood pressure in the arteriosclerotic cases was 16.5 points higher than in the controls, the average age at examination was 12.8 years higher. This, making allowance for difference in ages, would indicate that the blood pressure was but slightly higher in the arteriosclerotic cases. Similarly allowing an age compensation in making other comparisons, the question of blood pressure alone seems of little moment.

HEMOGLOBIN

A study of the hemoglobin gives negative results as the idiopathic, symptomatic and normal cases all had hemoglobin content between 85 per cent. and 86 per cent. Although the variations of hemoglobin percentage with age have been carefully worked out in the laboratory of this institution and are available, the age differences were so slight that this point is negligible.

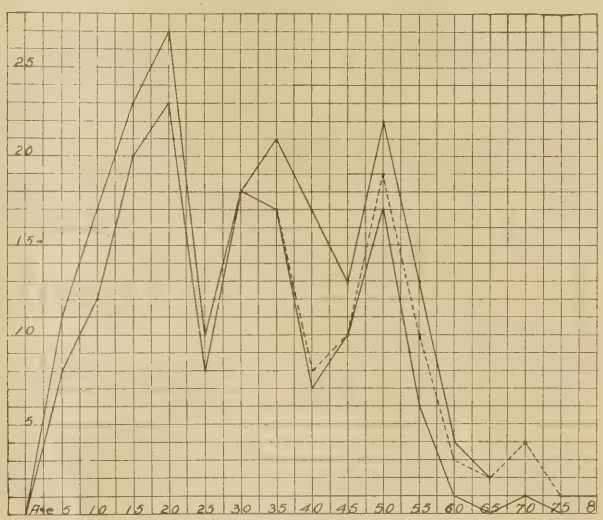

FIG. 1.—Chart showing age incidence of first convulsion. Upper solid line = Total number of cases in which age at first convulsion was known. Lower solid line = Idiopathic cases. Dotted line = Arteriosclerotic plus idiopathic cases.

ASSOCIATION WITH MIGRAINE

The coexistence of epilepsy and migraine has been frequently pointed out. In this series there was an incidence of eighteen in 157 cases, or 11.9 per cent.

DIFFERENTIAL BLOOD COUNT

This had been done in forty-seven cases. The following are the average results: Small lymphocytes 23.27, polymorphonuclears 70.42, large lymphocytes 4.23, eosinophiles 1.7, transitionals .23, mast cells .15, a total of 100 per cent. These are all within normal limits and the point apparently drops out of consideration.

FINDINGS IN X RAY OF HEAD

It has frequently been noted that pathology in the region of the sella occurs in some cases of so-called epilepsy. In the idiopathic series the results were as follows: Small sella, 3 = 6.12 per cent.; thick posterior clinoid process, 6 = 12.25 per cent.; both, 10 = 20.4 per cent; neither, 30 = 61.2 per cent. This means that the finding of a small sella, thick-

ened posterior clinoid processes or both occurs in about 39 per cent. of idiopathic epilepsy in this series. In twenty-nine of the symptomatic cases there were eight of such instances or 27.6 per cent.

There is a group of cases in which a factor was present which might have been etiological but the relation of cause and effect was not close enough to justify that conclusion. The convulsions in these began as follows: With influenza two, after eclampsia (several years) two, after alcoholic debauch two, after long severe labor (mother the patient) two, in presence of intestinal worms, ceased for years after ridding of parasite, but returned two, in presence of old skull fracture one, after electrical shock one, after rattlesnake bite one. But there are the following interesting features: One patient, after having had convulsions for years, was treated with rattlesnake venom and reported marked improvement. One of the so-called worm cases was that of a man of fifty-seven who "had never had epilepsy before." He had one convulsion a month until sixty-one, was then treated with medicine which rid him of the worms and he did not have another convulsion for twelve years. He then developed spells of epileptic automatism and marked mental deterioration. Further, the hereditary taint in this group independently was 57.2 per cent. Were they idiopathic or symptomatic cases?

SUMMARY

1. A series of 210 cases of epileptiform convulsions has been studied with a view of determining etiological factors. All points not comparable with recognized normal standards have been carefully compared with a series of two hundred consecutive nonneurotic cases.

2. No age is exempt. The curve of age incidence of the first convulsion shows three peaks, twenty, thirty to thirty-five, and fifty. The curve of symptomatic convulsion cases runs remarkably parallel to those of the idiopathic types.

3. Male sex predominates in the proportion of sixty to forty in idiopathic cases and sixty-six to thirty-four in the symptomatic. The latter is apparently due to the greater incidence of arteriosclerosis, toxemias, etc. in males.

4. Constipation is a marked predisposing as well as exciting factor or else epilepsy produces constipation.

5. The basal metabolism in this short series is somewhat lower in epileptics than normal.

6. Migraine headaches coexist with epilepsy in about 12 per cent. of cases.

7. The finding of a small sella, thickened posterior clinoid processes or both occurs in about thirty-nine per cent. of cases of idiopathic convulsions and in about twenty-eight per cent. of symptomatic convulsion cases.

8. Blood sugar, blood pressure, hemoglobin content, and differential blood count do not vary from the normal cases in epileptiform convulsions.

9. Since the symptomatic cases show an age curve similar to that of the idiopathies hereditary taint, constipation, sella turcica pathology and possibly lowered basal metabolism, nearly as great as that shown by the idiopathics, it would appear that the symptomatics are potential epileptics "waiting for" an exciting cause. If this be the case, the "cause" of a symptomatic convulsion is merely the exciting factor in the case.

Table 1. Hereditary taint in the various groups

Type	+	*Total*[1]	*Per cent.*
Arteriosclerotic	4	14	28.6
Intracranial pressure	5	8	62.5
Jacksonian epilepsy	2	8	25.0
Toxic	3	5	60.0
Hysteria	1	5	20.0
Total symptomatic	18	56	32.2
Idiopathic cases	58	143	40.6
Controls (Nonneurotics)	18	172	10.5

+ = Hereditary taint present in ancestors.

Epilepsy as a Type of Heredofamilial Degeneration or Abiotrophy

LELAND B. ALFORD, M.D.,
St. Louis

Turner says of epilepsy that it is as obscure now as when the lines of Lucretius' verse were penned centuries ago. Whether Turner's statement is literally true is a matter of opinion but certainly we are far from having a clear idea of the nature of epilepsy. The generally accepted facts of epilepsy seem to be chiefly of a negative nature; we at least know some of the things epilepsy is not. For instance, it does not appear to be an infection local in the brain or elsewhere or general; it is not a toxic condition; it is not psychogenic.

On the positive side there is the indubitable influence of hereditary tendency. This is evident in a percentage of cases sufficient to be conclusive it would seem in view of the limitiations of family histories and the percentage of cases in which other hereditary traits become manifest. That it is not convincing to many is inexplicable and may be an-

other instance of the common psychological phenomenon of overlooking the obvious, the unpleasant obvious.

If a conjecture may be hazarded as to one reason for the hesitancy in accepting the hereditary influence as final, it would be that the connection between an acquired illness and a congenital defect is not clear at a glance. One naturally looks for causes active near the time of onset. As possibly causal factors active at this time can frequently be found, such as overwook, an infection of some sort and so forth, there is little incentive to question their validity and to examine remote factors whose relation cannot be definitely established.

Nevertheless the fact remains that in weight and frequency inheritance overtops all other factors that have been mentioned. Such being the case, it is worth while to attempt to render relationships clearer by considering the mechanism by which the innate weakness may work to give rise to epilepsy some years after birth. What happens, for example, in the interim before the onset of attacks to transform the latent weakness into an active disease?

HEREDITARY DEGENERATION

The value of analogy in clarifying the nature of epilepsy has been consistently overlooked. It is obvious that if conditions of similar nature be examined together all will be better understood than if they are studied separately. And *a priori* the likelihood that the pathological process of epilepsy has analogies is very great. Of course there must be care and hesitancy in the selection of analogies and certainly there is greater safety in conclusions the larger the number upon which they are based.

The conditions which most closely resemble epilepsy are clearly the heredofamilial degenerations or abiotrophies. These generally show the influence of heredity, they are acquired, progressively increase in severity, and are organic in nature. Moreover, they are numerous and are particularly likely to affect the nervous system. No other type of pathological process than that here active so closely conforms to the accepted facts about epilepsy.

Here are a few of these abiotic degenerations: The progressive muscular atrophies and dystrophies, Friedreich's ataxia, paralysis agitans, Huntington's chorea, myoclonus, progressive cerebral diplegia, hereditary optic atrophy.

Upon examination of these conditions we find that pathologically there is a parenchymatous degeneration of cells and fibres of which no other cause appears than inborn weakness. The process is not always microscopically evident but its organic nature can rarely be doubted and where absent can be subsumed by analogy. The inability to find the changes under the microscope is easily explained; for instance, the degenerated cells and fibres may be so scattered that their loss is not detectable. In each of the conditions a particular set of cells and fibres is involved, the functions of these different sets determining the symptoms of the respective condition.

EPILEPSY AS AN ABIOTROPHY

In epilepsy, the chief function involved may be considered extra pyramidal motor in type. This motor feature can be plausibly regarded as in series with the tremor, the chorea, the athetosis, the incoordination and the hypertonus found in various of the other abiotic conditions. A defect permitting convulsions would not be different in principle from one resulting in chorea, athetosis and other extra pyramidal disturbances.

With the psychic features, consisting of the general deterioration and the tendency to the other well known deviations found in epilepsy, we have to compare the psychic features of Friedreich's ataxia, of cerebral diplegia, of myoclonus, of Huntington's chorea and even dementia precox itself. The type of psychic disturbance, like the type of motor disturbance, depends on the structures that happen to be involved in the degeneration. Whether the same structures are concerned in both motor and psychic disturbances cannot be stated.

Huntington's chorea is a particularly instructive analogy. Indeed it is the key condition which might have been divinely furnished to show us the way to understanding all the other conditions of this nature. The chorea is sufficient evidence of an organic process, of which the etiology is clear in the strong hereditary tendency. The organic nature of the mental changes is shown by the fact that they are associated with the chorea. Having Huntington's chorea in mind we can understand the motor and psychic aspects of epilepsy and also, for that matter, the psychic features of the true psychoses.

To return to heredity, there are undoubtedly aspects which are not yet clear. In the first place some of our conditions (for instance, progressive muscular atrophy) rarely give histories of familial occurrence and in line with these are the instances of the others when the closest investigation also is negative in this respect. Again the widespread occurrence among the races of the earth is against a purely hereditary origin and in favor of the frequent origin *de novo*. But whatever other process may be active, it clearly must be consonant with heredity. In this relation processes which may be considered are 1, the long remaining of a defective trait in latent state; 2, the transmission of certain acquired traits, and 3, the tendency of traits to become linked to functions (as occurs with the sex linked traits) and perhaps sometimes in transmission to jump from one function to another. Of course processes may be at work of which we now have no conception; but in any case we may be sure heredity has a part.

The foregoing observations are of course purely speculative. Nor in the present state of medical knowledge does there seem to be any way of verifying assumptions by direct observation. For instance in the matter of structural changes, no one can doubt that any amount of application of available staining or chemical methods will fail to disprove or confirm the organic nature of epilepsy. Still the value of the method of comparative study is clear, so clear that it is difficult to understand why it has been neglected.

SUMMARY

1. The contention is advanced that a great deal may be learned about epilepsy by considering it in relation to other nervous affections that seem to be of similar nature.

2. The affections most similar to epilepsy appear to be the heredofamilial degenerations or abiotro-

phies, examples of which are the muscular atrophies and dystrophies, paralysis agitans, Huntington's chorea, progressive cerebral diplegia, myoclonus, dementia precox, and other conditions.

3. In these conditions the pathological process is a degeneration of cells and fibres which arises from inborn weakness. In each condition a characteristic set of cells and fibres is involved.

4. In epilepsy the convulsions are assumed to be representative of a type of extrapyramidal motor involvement and to be in series with tremor, chorea, athetosis and incoordination which are types of extrapyramidal disturbance found in others of the group of abiotrophies.

5. The mental aspects of epilepsy are similarly considered to be comparable to the mental disturbances found in Huntington's chorea, cerebral diplegia and dementia precox.

6. The fundamental causative influence is heredity although other processes may act in conjunction with heredity as we now understand it.

Humboldt Building.

Anxiety Neuroses and Allied Conditions

R. B. TRACY, M.D.
Butte, Montana

No subject has occupied the attention of the psychiatrists to a greater extent in the last ten years than the study of borderland cases of psychoses such as the phobias, compulsions and anxiety states, and such cases while not always referred to a psychiatrist usually are for the reason that the general physician has not the patience nor the inclination to work along such lines.

Most physicians are able to distinguish the difference between neurasthenia and hysteria and to them there is practically no other psychoneurosis which is worthy of the name. If we accept neurasthenia in its narrowest sense it means nerve exhaustion and carries with it no ideas of fear, reference or obsession, but is a physical condition accompanied by various physical pains referable to the heart and digestive system associated with nervousness in the lay sense and insomnia, together with pressure headaches and carries no psychic manifestations other than the thought of extreme exhaustion. As neurasthenia is not to be considered in this discussion other than from a viewpoint of differential diagnosis I will leave that subject and look at the question of hysteria.

HYSTERIA

Hysteria was first described as a condition of nervous apprehension with certain physical manifestations causing paroxysms, certain degrees of unconsciousness with loss of memory and often associated with sensory disturbances and muscular contractions and usually was associated with some question of the individual trying to create a scene in order to gain sympathy. Freud exploded these doctrines and proved that hysteria was a psychogenic disease caused by fear, apprehension and remorse over sexual indiscretions or the thought of ever having been guilty of thinking of committing certain sexual irregularities; and it is the consensus of opinion today that hysteria is a psychogenic disease showing such physical signs and symptoms as before outlined. There is no doubt in the minds of psychopathologists today regarding the etiology of hysteria and all of the best authorities conform to the Freudian principles with slight variations. All are agreed that the sexual factor is the biggest and most important and in the majority of cases the agitator of the attack. We cannot eliminate certain inferiority complexes which engender a weakened resistance to mental conflict and thereby lower the threshold for future resistances in such a way that the patient becomes a mental coward.

These two conditions at one time were considered the only nervous manifestations to which the human was subject, but in the past ten years a wide field of investigation has opened up and our modern psychologists have separated and classified many milder psychic conditions which in some ways are allied to hysteria and in other ways are allied to neurasthenia. If we look at neurasthenia as the alpha of nervous conditions we may then consider hysteria as the omega of these conditions and that between the alpha and the omega are all of the various degrees and variations of psychoneuroses.

With this slight discussion of the two extremes of the psychoneuroses we are now better prepared to look into the anxiety conditions.

ANXIETY

Anxiety is a state of mind and is not a temporary but a continuous state of mind brought on by the emotion of fear. Christian Larson, one of our greatest psychologists, has made this statement, that fear is the basis of ninety per cent. of human ills. Whether this is true or an exaggeration of actual fact does not concern us but coming from such an authority would lead us to believe that it is somewhere near the truth even though expressed as hyperbole. That emotions are the basis of many of our diseases cannot be gainsaid when such authorities as Cannon, Langdon Brown and others have proven for all time the effect of fear, pain and hunger upon the animal mechanism and shown such influences on the internal secretions and the digestive fluids. If by emotions we can demonstrate in a few seconds anger with flushed face and contracted brow, and experience from this loss of appetite, headache and other somatic disturbance of either long or short duration, when we have the constant examples of people dying from fright or from joy, which is only momentary in its impression, when we have other and further examples of hair turning grey over night as is recorded by Hack Tuke in his book on *Mind and Body;* is there any reason then by which

we can further doubt that the emotions may cause serious somatic disturbance?

THE EMOTIONS

In order to cause a physical manifestation there must be a mental impression. If the emotions are the cause of these disturbances, they, being a product of the mind must affect the sphere of activity known as mental reaction. From such a discussion as we have been following there is but one conclusion to reach and that is that fear, being one of the emotions of every individual, engendered in life through prehistoric agencies from the eons of time, it must naturally be among the most primitive of all emotions. We fear the unknown or that which we do not understand, hence the reason for fear in childhood. If our education is neglected along sex lines from misinterpretation, prudery or any other cause, that libido being one of the most ancient of all emotions or trends, makes it easy for a psychologist to appreciate how sexual thoughts, whether brought to a culmination in an act or brooded over as thoughts only can cause a state of fear regarding consequences. The moment the cry for companionship, which is but a step to the sexual, as all modernists believe, is felt in the organism, there is a tension produced which must be relieved. Having been educated to believe that all thought of sex is wicked and that one who thinks in that direction is thinking sinful thoughts and realizing how inadequately they are prepared by biological determinism to resist this cry of the libido makes our young people apprehensive.

INCIDENCE AMONG SEXES

This will explain why it is that women are the most likely victims of anxiety neurosis, for women through their early education and home environment up to the present age have been denied that knowledge of sex to which they are rightly entitled and have been taught to suppress all thought of such matters as immodest. Knowing their actual and innate urgent desires in these matters they begin to realize the sexual conflict and many women are never wholly able to overcome or sublimate these desires to such an extent that they enjoy physical comfort. This is not so with men, because from earliest infancy from biological necessity men are constantly educated along sex lines, are never greatly restrained in their sexual desires and few men ever pass the age of puberty without having sexual experiences and relief from sexual tensions. Those who are unfortunate enough to be brought up in the wrong environment and who by such environment have become timid and retiring in disposition as the result are just as subject to the anxiety neuroses as are women who have been taught to suppress these physical tensions.

THE ELEMENT OF FEAR

To say that fear is always the result of a lack of knowledge of proper libido would be narrowing our topic and despite the Freudian theory we cannot accept it as final as the cause of anxiety neurosis, but we must be prepared to accept the fact that perhaps ninety per cent. of the anxiety neuroses are the result of disturbances of sex life.

Hecker, I believe, was the first man definitely to isolate and name this disease known as anxiety neurosis, and due to his long continued study of neurasthenia he was inclined to believe that it was an offshoot from a neurasthenic temperament, however, modern psychologists can no longer accept this as being true and Stekel of Vienna, a former student of Freud, accepts the fact that beside this condition each of the various psychoneuroses may show a relative amount of fear and a relative amount of sexual indiscretion. Through individualistic psychology we now find that the psychoneurosis may manifest as anxieties, phobias, obsessions, ideas of reference and amnesias, passing on through to complete unconsciousness. To come back to anxiety neuroses we must be prepared to accept the dictum of Ben Williams, who says that anxiety is nothing more than constant fear. Perhaps one fear, perhaps many fears started our neurosis. There is no doubt with the majority of cases the thing that started our fear was some inconsequential childhood impression with the lack of understanding that follows ignorance. If we do not succeed in recognizing and removing such fear thoughts, other associated thoughts ingraft themselves upon the original and we have a fear complex. Several fear complexes accumulating at different strenuous periods in life when we cannot adequately meet our conflicts produce that constant state of fear known as anxiety.

THE SEXUAL ELEMENT

In all of my individual experience with this type of neurosis I have never failed to find in an adult suffering from such a condition a sex element and in most cases the cause has been sexual tension from the lack of sexual gratification, started by deliberate intention, forced abstinence or psychic incompatibility. Symptoms of this condition may vary, they may carry with them many physical manifestations and to such an extent that the novice in psychology or a general practitioner may make the mistake of diagnosing the trouble as neurasthenia. One of the most common complaints in this type of patient is the feeling of tension in various organs, sometimes it is the urinary organs, sometimes constrictions about the chest, in others palpitations and arrhythmias and tachycardia. Very seldom in these cases do we find digestive disturbances, however, there is always some evidence of constipation. It is not difficult to understand these tensions once we appreciate the fact that the individual is suffering from continuous fear. We know that fear dries up secretions, we know that it produces apprehensiveness and when one is apprehensive it is not difficult to understand that there will be an acceleration in the heart beat. The somatic symptoms are always found in neurasthenia; the symptoms we do not find in neurasthenia are such as a fear of death, a fear of being left alone, a fear that the family will starve, a fear of imminent danger, a fear of suicide, and these are always present in the anxiety neuroses and are responsible for the name given the condition. If one is constantly apprehensive, constantly looking into the unknown for something which does not occur, living in mortal dread of imaginary consequences, how is it possible to be

able to sleep? Of all diseases which create sleeplessness there is none which is more decisive than that of the anxiety neurosis. It might be said that if you have not insomnia the case is not an anxiety neurosis, the very nature of the condition with its constant mental stress cannot help but induce sleeplessness. Where fears abound dreams of a disturbing nature are constantly present and in the anxiety neurosis they always have the sexual element either frankly presented or in a symbolic manner. As the sex life is the strongest contributary element in the condition we have a vicious circle which is hard to combat and one of the most stubborn of all types of psychoneurosis is that of the anxiety type. Had it not been for psychoanalysis perhaps we would never have recognized this condition as an individual and isolated state, but we extend thanks to Dr. Freud for this knowledge which has enabled us to segregate and classify this type of psychoneurosis and to give almost as definite an etiology to it as we would give to the cause of pneumonia.

As this paper can only deal briefly with any one of the phases of neurosis it would be very difficult to discuss even in a limited way such other conditions as obsessions, compulsions, transference and fixation hysteria, suffice it to say, however, that any one of these conditions may be easily taken for an anxiety neurosis and it requires great acumen, neurological skill and close observation before it is possible to make a differential diagnosis of these conditions. One of the greatest factors in these types allied to the anxiety neurosis is that they carry very little physical suffering and show very few evidences of lowered bodily resistance or insomnia, while in the anxiety neurosis these are most often the dominating symptoms.

CHANGES IN REACTION TYPES

It would not make this discussion complete without considering some of the after effects of these earliest types previously discussed. Compulsions may easily lead into hysteria, hysteria into psycholothemia and psychlothemia into a frank manic depressive insanity. Many of these psychoses were originally compulsions. Obsessions of all types while not disturbing the somatic mechanism are most likely to develop into paranoid trends with ideas of reference and persecution. Many of the pure anxiety types have been known to develop into melancholia with suicidal tendencies. This little diversion is brought up at this point in order to emphasize the fact that early recognition together with proper psychological and reeducational treatment will go a long way toward keeping numerous cases of this kind from developing into psychopaths and institutional cases. Mental hygiene, while very new, is the answer to the final solution of—What shall we do with these cases?

TREATMENT

Coming back to the question of treatment we have had various experiences with these cases and have learned beyond all cavil that medical and surgical interference has proven to be more detrimental than beneficial. We have learned that drugs and glandular therapy are only palliative measures and cannot be of any assistance in any psychoneurosis of long standing. No long continued insomnia has ever been reached through medicinal means, narcotics and soporifics have proved inefficacious in every single instance that I can recall. It is a far cry from drugs to psychology, but we must concede to the psychologist that he alone has been able to reach these conditions successfully. There are many methods of approach for treatment, such as the persuasion method of DuBois, the reeducational method of Morton Prince, the active analytic methods of various psychologists and all have given a relative degree of success, but it remained for Sigmund Freud and one of his older students, William Stekel, to demonstrate beyond all question of doubt that the most rapid method of approach as well as the most lasting result was only through psychoanalysis.

PSYCHOANALYSIS

It has been my pleasure to have proved to my own satisfaction that psychoanalysis is the specific for the removal of fears of every description as well as obsessions and compulsions and it has further been my experience that no method other than this as tried by myself has given permanent result. In a previous paper of mine on Epilepsy which was published in the *North West Medical Journal,* I called attention to the fact that psychoanalysis was constantly changing its procedure and that the technic was becoming ever more perfected. Even Freud himself made the statement that he was sure that psychoanalysis was in its infancy and his own pupil, Dr. Stekel, as well as Dr. Otto Rank, have proved that by a more perfected technic they can even reach cases of the milder psychoses. If through these means we can reach the nucleus complex and adjust conflicts which are the basis of psychoneuroses as well as of psychoses, is it any wonder that we have succeeded in curing ninety per cent. of the psychoneuroses which are only the determinants of psychoses if allowed to go untreated.

SUMMARY

First. Anxiety neuroses, phobias, obsessions, compulsions and transference hysterias all have a closely related etiology and most of them have their origin in sexual indiscretions and dissatisfactions.

Second. These conditions must be distinguished from hysterias at the one end and neurasthenia at the other end as having been intermediary processes between the two conditions.

Third. The symptom complexes of these conditions are practically the same with but slight changes in mental reaction and run the gamut from the physical, through the sensory into the mental.

Fourth. They must be definitely classified as distinct entities differing radically from both hysteria and neurasthenia, although having symptom complexes, some of which are common to both conditions.

Fifth. The rational method of handling these conditions is in a sense prophylactic rather than curative and to my mind this is the largest and most promising field of mental medicine.

Sixth. The treatment for all these conditions is the same and produces permanent results provided the nucleus complex is reached and the patient continues until dream processes show no longer sexual content.

Teaching Mental Hygiene to Medical Students and Practitioners

TOM A. WILLIAMS, M.B., C.M.
Washington, D. C.

An adequate conception of mental hygiene requires special preparation even beyond that of the medical curriculum. It was found during the great war that the chief handicap of the physicians assuming duty in neurological service was inadequate knowledge of the physiology of the nervous system, which requires for its understanding a better knowledge of its anatomy than is usual. The persons associated with the mental hygiene movement are too often deficient in this respect.

The best sanitarians have had an intensive bacteriological training, and all have a wide and deep knowledge of the natural history of infection, and most of them of immunity as well. Without this public health would not be so well safeguarded. We have as much right to expect a similar fundamental knowledge from those who undertake and conserve the mental health.

It is the absence of this knowledge on the part of the profession at large which has permitted the efflorescence of such vagaries of mental hygiene as Christian Science.

Adherence to the doctrine of Christian Science has caused obstruction to sanitary measures required for public health. The pernicious doctrine which animated the obstructionists was not refuted by the physician and other citizens who wished to adapt proper sanitary measures, because they are not versed in the fundamental facts of psychology requisite to refute the fallacies of cultists.

The same is true of suggestionism. The visit of its most recent advocate to America raised a wave of enthusiasm which was seldom quenched by a realization that that kind of suggestive therapeutics not only was dangerous because conducive to delay of adequate diagnosis in dangerous conditions, but that all kinds of suggestion had disadvantages which far outweigh the apparent and often spectacular removal of symptoms, which is so easy by that means to a skillful operator.

The unhappiness and even loss of life and moral decadence caused to the illadvised victims of lopsided theories of psychopathology has been observed by most discerning physicians. It is only one more example of the absurdities which have occurred throughout history in this sphere of what is known as psychology. From the incantations of ancient and medieval times to their pseudoscientific applications according to the theory of Mesmer through the esoterism attributed to the hypnotists, up to the absurdities just mentioned of our own day and generation.

To destroy these noxious germs the student of mental hygiene then must be prepared: First, by a clear conception of the physiology of sensation and perception and of the falsification of these caused by trauma, infections, intoxications, chemical perversion or other bodily disease.

This can be given in the medical school as at present equipped but only provided the knowledge is coordinated and applied specifically and orientated towards the conservation of mental health.

Just as a critical attitude in medicine is developed by exact work with physiological apparatus, so the present tendency to uncritical acceptance of unscientific pseudopsychology so rampant today even in the profession can be counteracted by a training in the psychological laboratory, when that is properly orientated towards showing the student how ill-founded are many of his ideas not only about the behavior of others but even about himself: Even the simple ascertaining of the true reaction time bristles with fallacies, the study of attention shows the student how easily it lapses and shows the class its differences among individuals, and when one reaches the most difficult study of all, that of introspection, which is the chief avenue to the mind of patients, a whole world of difficulties is opened up, the learning to cope with which, however, is one of the essentials of a good psychiatrist. A proper laboratory course then teaches the student to avoid the easygoing generalizations which pass current among the uncritical.

Furthermore the further study required for an adequate grasp of psychological processes is rarely given even in the depatment of neurology and psychiatry. The reason for that is that the concern of the holders of those chairs is usually with the grosser types of disease such as come to the hospital and madhouse. Only recently have they begun to be interested in the processes which lead to the gross deviation of conduct called by the laity insanity. The departition and selection of types of disease under labels has preoccupied them too much.

The tendency to lean upon authority instead of thinking for oneself, an infantile characteristic, is supposed to be bred out of one during a scientific training, which that of a medical student is supposed to be; but alas! the investigation spirit is the exception even among doctors, in spite of the innumerable incentives thereto which their work showers upon them, particularly in psychiatry.

Against this fatal tendency the student of mental hygiene must be assiduously guarded by the teachers by their avoidance of the assumption of infallibility. This is best secured by means of an abstention from the didactic method, by the giving to the students of the explicit objective to understand mental processes through the avoidance in their earlier studies of searching for type diagnoses, or to give textbook names to the diseases of patients.

The best way to attain these aims is by allowing the student to work with patients before he has read or heard descriptions of mental disease. This should be an analytic exercise with no pretensions to completeness, but with a single objective, i. e., the search for a particular abnormality by the patient, e. g., a peculiar motivation, or an unusual state of feeling, or an intellectual defect, or an unsocial tendency, as the case may be. These elementary

exercises should be pursued until the student develops an exploratory technique and an attitude of interest in the study of the mental processes of his patients.

The second step in education of the student should again be undertaken upon patients. In the grouping together of findings of the foregoing kinds into the more complex mental attitudes and affective states.

Only after this has become a habitual clinical method should the use of the conventional nosologies be introduced as a final step in preliminary psychiatric training.

The student is now furnished with the rudiments of the understanding of mechanisms and habit of thought which compels him to seek them.

By knowing how diseases develop, he has the first requisite for stopping their development. Whereas formerly he could only stop disease by destroying its bearer, just as a person ignorant of photography could only arrest the development of a photograph by wiping it off the plate, while one who understood the chemical process could modify its development in any way without destroying the photograph.

After understanding psychopathological processes through the study of patients, the student will begin to study the sociological factors which contribute to mental disturbance in various ages and conditions such as in infancy, childhood, adolescence, youth, marriage and in the various industries and occupations of life.

In clinical study some understanding is gained by the inspection of an incompetent mitral valve, an acute nephritic kidney, an advanced cirrhosis of the liver or a sclerosed spinal cord; but the physician who stopped here would be a poor diagnostician except of advanced cases without hope. The really useful physician is he who could diagnose these conditions in their incipiency, to do which he would have to understand far more than the morbid anatomy of the ultimate process.

This is just as true of mental disease. An advanced dementia in the asylum, or the last stage of paranoia, extreme melancholia, or acute mania is comparable to dead house material and poorly adapted to instruct the student of processes. Disease does not begin in a hospital, so to study its incipiency the dispensary must be frequented and the home visited. The laboratory of mental hygiene is the hospital dispensary. Few patients in any of these services fail to present some aspect of interest to mental hygiene. So the psychiatrist in charge should be in the closest cooperation with the directors of the other services as the most fruitful clinical material may come from the most unexpected sources.

For example: A complaint of blindness may be due to the motivation of a desire for sympathy, ophthalmological service. Impotence may be the fruit of phobia, or sense of superiority. Aphasia may be assimilation of shame. A pain in the back or limping may be a reaction to painful circumstances. Vomiting may be the manifestation of a disgust complex. Tachycardia may be the fruit of emotion. The medical service is full of examples of psychopathological signs with physical symptoms which are problems of mental hygiene.

To graduates, the difficulty in teaching mental hygiene is that what we may call the functional point of view is so often beyond their ken. The operating room and the dead house have trained them to think more statically than dynamically. This obstacle, however, has already been overcome in clinical medicine by the study of body chemistry. To overcome it in psychiatry the analytic study of patients is the best preparation; but they must be patients in formative stage at least (dynamic) and their motivations and feelings should not be too remote from those of the healthy individual, for the earlier studies at least. Not the dramatic and astonishing, but the simple and usual is the suitable paradigm for the instruction of the beginner.

When the concept of psychogenesis has been thoroughly grasped and put into clinical practice there exists a real danger both in the case of students and graduates that to the psyche will be attributed disorders of quite other origin.

This failure to detect physical origins is of course the dominant vice of the psychic cultist or others who attempt to treat the sick without the adequate preparation of medical training. It can only be counteracted by the clinical knowledge which is gained in dealing with patients by the method of intensive study during the preparatory period. Not the number of cases seen, but the thoroughness with which each is studied is the maker of clinical power.

Hence abundance of patients in the teaching of mental hygiene by means of psychiatry is a drawback rather than an advantage, unless there is a staff large enough and accomplished enough to deal with large numbers. Thus no hospital clinic need be too small to furnish examples sufficient for a class of students, as each patient may afford material for study for weeks, especially if the social and industrial relationships of the patient are included in the study, as they should be.

There should hence be a close and intimate connection between the mental hygiene clinic and the social service department of the hospital when there is one, and if one does not exist the mental hygiene clinic would become in effect a social service if it is adequately conducted.

SUMMARY

The teaching of mental hygiene requires:

1. Adequate knowledge of the physiology of the nervous system, presupposing its anatomy.

2. An adequate knowledge of dynamic functional psychology.

3. The clinical study of these upon the elementary processes on patient to the exclusion at first of their synthesis into the current appellations of mental disease which is most satisfactorily performed in the dispensary and hospital in preference to the asylum for the insane.

4. The study of these processes from a social point of view in home, school and workshop.

5. The knowledge of the dead house types seen in the asylum.

Practical Therapeutics

SOME USES OF INSULIN

Joseph F. Bicak, M.D.
New York

Insulin was at first intended only for the treatment of diabetes. Already it is used by some for the treatment of tuberculosis, acidosis and hyperthyroidism, and good results have been asserted. It is the purpose of this paper to call attention to other possible uses. From the beginning of the practice of the healing art, it has been the custom to inspect the patient's tongue, in order to judge by its appearance, especially the coating, as to the condition of the stomach, and the severity of the disease. It has also been the custom to give medicine to make the bowels move more. Usually this was done as a matter of routine. One of the objects of this treatment is to keep the digestive organs in better condition. Most physicians believe in this procedure. The fact that these customs are practically universal shows their importance. When the bowels are moving well, the physician believes there is less danger of autointoxication, and when the tongue improves in appearance, he believes the digestive organs are functioning better, and usually, that the disease is improving.

If any other method of treatment could be found to put the digestive organs in better condition, it would be a valuable help to say the least. It would increase the resisting power of the patient, shorten more or less the period of illness and convalescence, to say nothing of the effect on the death rate. It is well known that insulin improves the appetite. It is reasonable to believe that this is evidence of better functioning by the stomach, and that the pancreas is not the only organ to be favorably affected. This raises the question as to whether other digestive organs are not also benefited. If this action of insulin can be obtained to any appreciable extent in acute diseases, and in chronic wasting diseases, then its field of favorable influence becomes very large, and it becomes a very important remedy aside from its use in diabetes. That this is so is indicated by the following cases.

Case I.—Male, aged three, pale, thin, one cervical gland enlarged to the size of a hazelnut, mother complained principally that he had a poor appetite for a very long time, received an injection of one third unit of insulin. A week later the father stated that the boy asked for something to eat a few minutes after the injection, and also said that he was hungry, something that he had not said for a long time, and that he continued to have a good appetite up to the time of the father's report.

Case II.—Male, aged twelve, acute rheumatic endocarditis, pericarditis, dilatation, râles all over both lungs posteriorly, 102° F., respiration 56, coated tongue, looked extremely sick; one unit of insulin daily. Improvement was slow but the tongue was noticeably less coated within two days and the appetite also improved quickly. It seemed that the insulin was an important factor in the general improvement.

Case III.—Male, aged forty-nine, chronic malaria, mild symptoms, those referred to the digestive tract becoming very annoying now and then. The latter were an uneasy sensation in the abdomen after meals, sometimes amounting to actual pain, and occasionally a slight nausea. One unit of insulin relieved these symptoms for about two days at a time.

It may prove to be of some value in malignant cases and those where the stomach rebels against quinine. This would also apply to other diseases and remedies which annoy the stomach.

Case IV.—Female, aged twenty-four, mild case of rheumatic fever, tongue coated, complained also of loss of appetite, received one unit of insulin daily. Although the slight elevation of temperature continued for more than three weeks, all the symptoms improved during this time, but the appetite and coating of the tongue improved much more promptly than the rest.

Cases V, VI, VII, and VIII.—Four patients with scarlet fever. All the children were given a fraction of a unit of insulin daily, and were taking food well before the temperature became normal.

Case IX.—Female, aged twenty-four, severe infection of throat with false nondiphtheritic membrane on both tonsils, temperature as high as 105° F. at beginning and lasting ten days, was given two thirds unit insulin daily, appetite returned on fifth day.

Case X.—Female, aged one, otitis, canal full of pus, teething, temperature 105.6° F., given one sixth unit insulin daily. After four days, all the symptoms were improved and the appetite was good, although the ear was still discharging freely, and the temperature was not quite normal.

Case XI.—Male, aged ten; pneumonia, coma, meningismus very severe, given two thirds unit insulin daily, good appetite on third day, temperature normal on fourth.

Case XII.—Premature baby, five weeks, four pounds, lost eight ounces in the last week, was put on formula in addition to breast, given insulin one eighth unit only once, gained ten ounces in four days. The weighing was done by an experienced nurse and the appearance of the baby's face was a strong corroboration of her figures. Insulin should be very useful in these cases, also in difficult feeding cases in full term babies. It may become popular in infant clinics.

Case XIII.—Female, aged sixty-six, lobar pneumonia, infected kidney, emaciated. It seemed well to warn the family that she was not likely to live more than a few days. She received by far the largest amount of insulin of all the cases, as much as five units a day when at her worst. Her family was surprised at her appetite, and she survived the crisis on the tenth day, although the temperature rose again immediately on account of the complications, and she still has fever on the thirty-second day at time of writing.

Case XIV.—Female, aged three, pertussis, received one sixth unit insulin daily at first, less often

later, did not lose her appetite as so many of these cases do.

Case XV.—Female, aged one, acute cervical adenitis, temperature 103° F., given one third unit insulin. Next day the temperature was normal, the glands of about the same size and the appetite had returned.

Case XVI.—Male, aged forty-five, severe diarrhea for ten days, temperature 99° F., stools were reduced from nine to four in twenty-four hours, and to normal in forty-eight.

Intestinal cases may become another excellent field for this treatment. It should be given a trial in cholera infantum, Asiatic cholera, yellow fever, typhoid, dysentery, colitis and other conditions, also in the vomiting of pregnancy and after operation. There are probably few conditions of the stomach and intestines in which it would not do some good.

In several cases of essential hypertension in which the improvement from treatment with sensitized colon vaccine seemed to have reached its limit, the addition of insulin seemed to help to start further improvement. The following case is an example.

Case XVII.—Male, aged fifty, had a blood pressure of 186/90 on December 22, 1924. This was reduced to 170/86 on April 20, 1925, by weekly injections of sensitized colon vaccine.[1] It had not gone below this point at any time. Then the insulin in doses of one to two units was added and the pressure was reduced to 150/76 on June 23, 1925, at time of writing. If this treatment continues to produce such results, it will be evidence that the poison causing essential hypertension comes from the intestinal tract.

In urgent cases of many kinds, the intravenous injection of glucose solution with larger doses of insulin may prove extremely helpful.

Action of Insulin on Nitrogenous Metabolism.—Henri Labbé (*Bulletin de l'Académie de médecine,* June 17, 1924) found in experiments on dogs that normal metabolism is accelerated by insulin and that the reserves of nitrogenous compounds in the body are used up in consequence. Nitrogen balance previously attained on a definite diet is upset and is not restored as long as the insulin injections are continued. The excess of nitrogen passing out in the urine may amount to thirty per cent., or even more, of the total nitrogen in the diet. The animal's weight falls, though not as conspicuously as the nitrogen in the urine rises. The chemical form in which the excess of nitrogen elimination takes place does not seem to deviate much from the normal. The excessive nitrogen elimination is induced by as little as 0.6 physiological unit of insulin per kilogram of body weight, and increases with the dose given. There is little discomfort at first, but later there is intense thirst, and if large doses are given at shorter intervals, the animal dies in a condition of cachexia. The disturbance of nitrogenous metabolism due to insulin is less under a sufficient, balanced diet of proteins, fats and carbohydrates than where the carbohydrates are reduced and then omitted, though calorically compensated for by increased allowance of fats. Under the latter conditions a greater amount of nitrogen is lost and the animal dies in cachexia. While it disturbs normal nitrogenous metabolism, insulin seems, on the contrary, to improve abnormal nitrogenous metabolism. In the cases of diabetes in which there is cachexia with exaggerated consumption of tissue nitrogen insulin not only checks the loss of weight but often results in a marked and rather rapid gain in weight. General metabolism is improved, assimilation increases, and acidosis diminishes or even disappears.

Blood Changes and Clinical Symptoms Following Oral Administration of Phosphates.—Harold A. Salvesen, A. Baird Hastings, and J. F. McIntosh (*Journal of Biological Chemistry,* June, 1924), observed after the oral administration of neutral phosphates in small doses over a long period a considerable increase in the phosphates of the serum, accompanied by a decided drop in the calcium (about seventeen per cent.). There was also a considerable drop in the magnesium and chlorides. Alkaline phosphate produced no change in serum calcium, and only a slight increase in the phosphate content; sodium and CO_2 content increased considerably, while there was a slight decrease in chlorides. The alkalinity of the blood was observed to increase somewhat. Acid phosphate produced no appreciable change in the calcium content, but a marked increase in the phosphate content. In none of these experiments were there any clinical symptoms. Large doses of phosphates administered over a short period of time produced most violent clinical symptoms, independent of the pH of the solution used, and which had the characteristics of the socalled tetany; the serum phosphates increased and the calcium decreased, as did the magnesium content of the serum. The injection of calcium chloride checked all the symptoms and produced an increase in the serum calcium. The conclusion is reached that the clinical symptoms (tetany) produced by the oral administration of phosphates are due to a reduction of the blood calcium.

Functional (Nervous) Digestive Disturbances.—Heinrich Schur (*Wiener klinische Wochenschrift,* November 27, 1924) calls attention to the nervous and endocrine influences on the intestines. In Addison's disease the influence of the parasympathetic system is seen in the diarrhea and vomiting. The influence of the thyroid gland is seen in the diarrhea of exophthalmic goitre and in the therapeutic test of thyroid extracts in certain cases of constipation. Mucous colitis usually occurs in women, in whom the ovary is usually pathologic. The same may be said of dyspepsia and the abnormal pains observed in young girls. In this group, as well as in migraine, vomiting is very troublesome. The author believes that these sensations are localized in the diencephalon and that they originate in the organs in which the assimulated food is deposited—especially the liver. The possible diagnostic significance of hunger and the feeling of satiety is underestimated. The fat tissue in these persons may be unable to increase the deposits, and may therefore cause a lack of appetite for food. Thin people may eat little because they are thin. Dyspepsia is frequently of purely psychic origin, but it may also be a sign of beginning mental disease.

[1] Treatment described in the New York State Journal of Medicine, March 13, 1925.

Historical Medicine

A Brief Survey of the Evolution of Therapeutics*

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

As the treatment of disease is the fundamental aim of medicine, it seems proper that a brief summary should be given of the evolution of therapeutics.

Immediately after its birth, treatment of disease was entirely empirical, but gradually enriched its practice by experience that had been found fruitful. The Babylonians placed their sick in the public places and highways and sought advice from passers by who might have seen similar cases or know of some remedy that might bring relief. The Egyptians, to whom the creation of medical science must be attributed, were also the creators of pharmacy; they employed liniments, tonic potions and plasters, and used laxatives and enemata, but to this empirical treatment they added sacred ceremonies, incantations and magic, a fact which proves that suggestion has been found of value in all times and in all places.

GREEK MEDICINE

The Greeks, who borrowed their first medical knowledge from the Egyptians, began by resorting to suggestion; they treated internal diseases by prayers, charms and votive offerings, limiting medical practice to the dressing of ulcers and wounds. But hydrotherapy lent its aid to suggestion and it is said that Melampous restored to sanity the daughters of Proetus, who were afflicted with mental disease, by means of sacred ablutions and purging with hemlock.

In the temples, which began to be erected about the XIIth century before Christ in different parts of Greece, such as Cos, Cnidus, Rhodes, Epidaurus and Pergamos, the Asclepiades preserved secrets of therapeutics richer in dreams and visions than in medicaments. They took oath never to reveal their knowledge, but, as the practice of the healing art gradually became more logical, secrecy was relaxed and in the VIth century before Christ Pythagoras wrote a book on the properties of plants and on the use of scilla. At this time hygienic measures, diet and gymnastics were more especially employed, but later on they were eliminated from treatment, again to be employed in our day.

A century later Hippocrates brought together all the books pertaining to the medical knowledge acquired before his time, thus erecting a monument which after twenty-four centuries is still the admiration of all who know it. But it was not Hippocrates who enriched therapeutics; he has given us no new medicament, but he founded the science of dietetics, and from the very start he brought it to such perfection that even today there is little to be added. His medical system, which, from the viewpoint of the cause of disease, is vitalism, and from the point of view of the effect is humouralism, should not allow us to forget that he was the first to invite us to empiricism, when he says: "In medicine we do not think that it is proper to have recourse to hypotheses; the unknown should be reached from the known; teaching should be accepted from the most simple men if they appear to know something decisive in respect of a given thing. It is thus, I believe, that our art has developed. Great attention should be given to what happens by chance, if the phenomenon can be confirmed upon several occasions."

Yet two centuries passed by before Philinus of Cos and Serapion of Alexandria formulated the laws of empiricism. The recognized three sources of study, namely, chance which furnishes the facts, experiments which make it known if it is possible to reproduce these facts, and lastly by the analogy by which may be applied to recognized procedures useful in the two former means when applied to a similar case. Archagathos (219 B. C.) introduced Greek medicine into Rome, but his popularity failed on account of his brutal methods of treatment. In the following century Themison developed Methodism, in which treatment was extremely moderate. He attributed all disease to *strictum* or *laxum,* but this fact did not prevent him from the practice of empiricism, like his predecessors, in every case where he could classify a disease in the too narrow limitations of his doctrine, and this must have happened very frequently to him.

Athenaius (69 B. C.) founded the Pneumatic sect, of which Plato and Aristotle had been the forerunner, and had as disciple Aretaios. Pneumatism passed like a breath of wind over Empiricism, which was in no way shaken, and was extinguished, only to reappear with Stahl under the name of Animalism towards the end of the XVIIth century.

During this time pharmacy prospered at Rome and materia medica was enriched by new acquisitions. Its herbal which was then most varied included among the active plants aconite, poppy, henbane, hemlock, hellebore, and many others. From the mineral kingdom it took arsenic, antimony, iron, the sulphate and acetate of copper, the carbonates of sodium and potassium, nitrate of potassium, alum, calcium, gold and silver. The animal kingdom furnished their materia medica with cantharides, salamanders, and vipers, and it also utilized mineral waters which were divided into sulphurous, aluminous, saline and bituminous. It is, however, only right to say that aconite, arsenic, the solanaceæ and vipers were first employed as poisons before becoming remedies and that physicians received them directly from the hands of the magicians and sorcerers.

Encouraged by the exigencies of a rich clientèle, who wished only to take expensive remedies, polypharmacy set itself no limits, and he had the most

*The concluding lecture to the Elementary Course on the History of Medicine in the University of Geneva, delivered July 11, 1925.

success who could invent the most extraordinary medicament. Andromachos of Crete, physician to Nero, compounded a remedy composed of seventy-eight different ingredients, in fact all the materia medica of his time, and called it theriaca, which we may rightly assume to be the masterpiece of Empiricism. Be this as it may the theriaca went down the centuries and was even used in the middle of the last century, and even the great Trousseau advised its exhibition in confluent smallpox, serious types of measles and other forms of malignant fever.

Galen then appeared to put a little order into the progress of medical science, which was going astray in the realms of fantasy. He revived the doctrines of Hippocrates, namely the four cardinal humours—blood, pituit, bile and atrabile. When blood was in excess plethora developed and when either one of the remaining three was in too great abundance cacochymy ensued. To revive the doctrine of Hippocrates merely meant that Empiricism was given new impetus. Galen's therapeutics were in no way original and, although he certainly deserves his reputation as a skillful and lucky physician in the treatment of his patients, his success was due to the fact that he had good judgment in the use of medicaments invented before him.

After Galen, during the decadence of the Roman Empire, therapeutics also fell to a low level and the reader will probably remember that Aetius of Amida (502-575 A. D.) treated his patients by incantations. At practically the same period Alexander of Tralles (525-605 A. D.) went to the opposite extreme and invented a treatment consisting of three hundred and sixty-five potions that were to be taken by the patient during a period of two years. During the long night of the middle ages, Arabia was the only refuge offered to the luminaries of intellectual life, and, as we have pointed out, the Islamic physician contributed largely to the progress of pharmacy, or it may not be too much to say that they created it in the scientific sense. It may unhesitatingly be said that they perfected it to such a degree that the discoveries of modern organic and inorganic chemistry were necessary to bring it back to the level to which they had raised it.

We know that Avicenna gilded and silvered his pills, that he made extracts, syrups and electuaries whose delicate manipulations must have delighted the pharmacists of only thirty years ago. The Islamic physicians were familiar with the alembic and Abulcacis from its use discovered alcohol of wine. Without referring to the many substances derived from the mineral kingdom which were unknown up to their time, we will simply say that the Islamic physicians published a codex which regulated the use of medicaments and any new product could not be prescribed without the permission of the government authorities.

But the mysterious, the inexplicable and the impossible attracted them. Abulcacis attempted the transmutation of metals and although his researches and those of other alchemists have largely contributed to the discoveries and the progress of chemistry, the same cannot be said of the labor expended in the search for the elixir of life, whose study excited the enthusiasm and ardor of this learned man and his many disciples. These researches absorbed considerable intellectual force which, had it been rationally directed, certainly would have aided the progress of therapeutics, which was still in its infancy.

We will not stop to examine the Code of Health in which John of Milan translated the precepts of the School of Salerno in leonine verse. Leaving aside the stagnant treatments of the middle ages and coming to the Renaissance which was dominated by that impetuous individual, the destroyer of genius, namely Paracelsus, let it be said at once that the glory of Paracelsus is a result rather of his genius than of his destructive brutality, for the edifice built by Hippocrates and Galen still remains almost intact in spite of his attacks upon it, while the building of which he himself laid the foundation has endured through centuries and is added to every day. He sowed the first seeds of medical chemistry, which had no existence before him; and he strongly advocated the use of antimony, iron, lead, arsenic and mercury—the specific of syphilis—which remain now and will probably exist for a long time to come as the last trench of Empiricism to be taken.

Paracelsus tells us that "experience has shown that mercury is the sovereign and only remedy for the cure of all ulcers tainted with the great pox. Sublimated mercury has been retained in this business as a general remedy because its great virtue has been known to everybody. It is given by mouth and cures by inducing abundant expectoration of saliva, not because the saliva is the cause of the disease but because it is mixed with it."

Paracelsus also referred to the extraction of the quintessence of plants, but this was only accomplished at the beginning of the XIXth century when P. J. Pelletier and his collaborator, Caventou, prepared sulphate of quinine and afterwards proceeded to the extraction of vegetable alkaloids.

Paracelsus even foresaw the practice of asepsis, for he says: "Do not touch wounds, as they cure themselves; it is the external agents which militate against the process of cicatrization. He inaugurated an ingenious diagnostic method still used today for the diagnosis of indefinite syphilitic manifestations, and he affirmed that by the nature of the remedy one might determine the nature of the disease. Although it must be admitted that the mental equilibrium of Paracelsus was far from perfect, he certainly gave a great impetus to the progress of medicine, but he was led astray by the occult sciences, delved deep in the Arcanums and dallied with researches for the discovery of mysterious panaceas complicated with astral influences, while on the other hand he foresaw with a marvelous lucidity of intelligence the why of things which were still hidden in obscurity, and he says: "Before the end of the world a large number of supernatural things will be explained by physical causes."

While anatomy and surgery, the despised legacy of Herophilos and Erasistratus, progressed by the work of Vesalius, Eustachius and Fallopius, therapeutics lay dormant as if exhausted by the sudden impulse given it by Paracelsus. We will now go on to the XVIIth century, when under the fertile influence of the philosophy of Descartes, new doctrines sprang to life. Empiricism had continually progressed since the days of Hippocrates and experi-

mental science had likewise been considerably enriched. The number of known diseases had been increased and with them both medicaments and medications. Having nothing to guide them, having no positive method, ignorant of pathogenesis, deprived of experimental physiology upon which certitude could be based, physicians of these days had only their memory to resort to, and therefore filled their minds with as many facts as possible so as to be able to find them again should a similar case present itself. Certain partial theories existed as well as some special opinions relating to a given organ or a given viscus and from these theories a logical medication could be derived without resorting to Empiricism.

But these theories and opinions were fantastic and reference to a single one will be quite sufficient as an example. In the days of Hippocrates the uterus was regarded as an animal who could be flattered and attracted by pleasant odors, while it disliked fetid odors extremely and attempted to escape from them, so that in the middle of the XVIth century we find Amatus Lucitanus treating a uterine prolapsus, as he thought, with considerable ingenuity, by causing his patient to inhale musk and pleasant scented herbs in order to attract the uterus upwards, while the vulva was exposed to the stench given off by galbanum and the smoke of burning feathers in order to cause the displaced organ to recede. As is seen, Empiricism at this time was preferable to the therapeutics of sophism, but they had commenced to become weighty and the medical profession, wearied of always referring to memory, felt the necessity for a method which would have as a starting point really rational treatment.

It was then that Borelli developed the Iatromechanical doctrine, according to which all physiological and pathological acts could be reduced to a system of movement, or shock, balancing, pressure and relaxation. During this time Sylvius founded chiniatry in which chemical agents were preferably employed. This doctrine, the germs of which had been planted by Rhazes and developed by Paracelsus and the Spagyrics, attributed disease to acridity. This acridity could be either acid or alkaline, and was treated by contrary chemical medication, which singularly simplified therapeutics, but of course was absolutely insufficient.

A little later Baglivi attempted to resuscitate the *strictum* and *laxum* of the Methodists, but he does not appear to have been very convinced, for he says that many different theories respecting diseases and their treatment can be put forward, and that if any one of these theories represented all the known facts, any one of them would be able to produce a cure. As can be seen, this merely complicated the question by attempting to simplify it. Baglivi studied the question of revulsion with cantharides that even the prudent Hippocrates had given internally in cases of hydropsy. Baglivi was fearful of the use of cinchona in cases of malaria and preferred sal ammoniac and camomile. This man, who wished to overthrow Empiricism, was in reality a retrograde Empiricist.

His contemporary, Boerhaave, became the apostle of the iatromechanical theory to which we have just referred. In his youth he suffered from an ulcer of the thigh, for which all treatment, carried out for four years, had proved fruitless. As a last resort he decided to treat his ulcer with urine, because it contained salts insolution. For all this Boerhaave became a renowned practitioner and inaugurated clinical teaching by the bedside.

Boerhaave taught that there was a salt, putrid, and oily temperament. These temperaments in reality represent what today we call diatheses, the oily temperament being arthritism, in other words a general condition in which the functions of the organism work imperfectly. His treatments, which, it appears, ought to have been tonic and stimulant, were rather depleting and debilitating, and were selected from among purgatives, alkalines and sudorifics, diatetics and blood-letting, with a good dose of suggestion added.

In order to oppose the iatromechanical doctrine, G. Stahl created animism, which was merely a perfected pneumatism. He admitted three movements in the body, namely the circulatory, secretory and excretory. The soul presided over these movements for the regulation of the equilibrium in health and to correct this equilibrium in disease. This theory would seem to imply a psychical or suggestive treatment, but such is far from the case. Stahl's therapeutics were those of the Empirics of his time, although he was moderate in the use of remedies and it is only just to say that in cases of fever he did not exhibit cinchona bark but followed an expectant plan.

And lastly, when organic dynamism, developed by Frederick Hoffmann, has been mentioned, it will be seen that, although the XVIIth century did not bring forth the doctrine which might have been expected, it at least attempted to produce it upon several occasions.

Bordeu gives an excellent outline of the condition of Empiricism during this time and he says: "The king appointed a royal commission with the king's physician as its chief. This commission was intended to collect and examine the empirical remedies and then to select the most useful among them. It was from this school, or rather court, that the majority of remedies employed today (XVIIIth century), such as mercury, tartar emetic, various neutral salts, cinchona, ipecacuanha, kermes and so many others are derived, which finally oblige the Dogmatics to remain in their entrenchments."

Inoculation of smallpox, which would soon be succeeded by vaccination due to Jenner, had been transmitted throughout the ages among various peoples, and Lady Montague, having had her son innoculated, thus introduced the practice from Constantinople into England. Thus we have confirmed the aphorism of Hippocrates: "The medical art is formed little by little and daily becomes enriched by new discoveries; it cannot arrive at the highest point of its perfection until a great number of generations have come and gone."

Two medicaments are to be particularly noted in the therapeutics of the XVIIth century, namely antimony, or rather emetic, which, after savage attacks and passionate eulogies, at last became admitted into materia medica and continued to render great service in the treatment of disease; and cinchona, which was introduced into France and Spain in 1679. This

specific of Paludism took its place beside the specific of syphilis, thus enlarging the field of empiricism, and continued to be one of the great glories of empiricism up to the year 1882, when Richard demonstrated the parasitic nature of intermittent fever, while Laveran distinctly established its pathogenesis, hence transplanting the Jesuit's powder from the domain of empiricism into that of pathogenic therapeutics, which were beginning to develop.

As may be seen, the struggle against Empiricism in the XVIIth century was not extremely successful; the iatromechanists, the chimiaters, the animists and dynamicists had completely failed in their attempt at substitution. The XVIIIth century gave evidence of greater prudence. It produced no Colossus and even seemed resigned to accept the domination of the past; but beneath the silence it was forging invincible weapons which would be used by the XIXth century to assure the triumph of new therapeutics.

HISTOLOGY

Leeuwenhoeck created micrography, which was soon to be used by Bichat for opening up the road to an unknown science, namely histology. During this time von Haller laid the foundations of physiology and Lavoisier placed chemistry on the solid and unshakable basis which Paracelsus had foreseen rather as a therapeutist than as a scientist. The ideas of Paracelsus had brought forth fruits which would be plucked in the XVIIIth century, for at the time when Lavoisier formulated the laws of chemistry, a physician brought back into favor a medication which had been created by Paracelsus—this physician was Mesmer, and his medication was animal magnetism.

However, the end of the century was to be marked by a discovery of the highest importance, namely vaccination, performed by Jenner for the first time on May 14, 1796. The youngest daughter and the greatest glory of empiricism, vaccination took its place at the head of specific remedies, while at the same time she opened up the road to an entirely new medication, namely prophylactic therapeutics. Later on, we shall see how, under the influence of the discoveries at the end of the XIXth century, it overthrew the very doctrine to which it owed its birth.

CLINICAL STUDY

From the beginning of the XIXth century advantage was taken of the work of the preceding centuries. Clinical observation, systematically established by Boerhaave, developed greatly and increased its means of investigation; as early as 1674 Thomas Wilis had noted the presence of sugar in the urine of diabetic patients, while in 1726 Dekkers discovered albumin in the urine. But it was Laënnec who, by his discovery of auscultation, brought clinical medicine up to its present level. His precision in investigation limited the field of empiricism.

HOMEOPATHY

Then Broussais appeared upon the scene with his theory of excitation. According to him there was but one pathogenic agent, namely excitation. This could show itself in two ways; if the excitation was too weak, debility ensued, while if it was too strong it resulted in irritation. In his therapeutics it would seem that Broussais neglected debility and directed his attention especially to irritation, which he treated by debilitating remedies derived from empiricism. Opposed to the doctrine of excitation a new doctrine was developed by Samuel Hahnemann, the essence of which was *similia similibus curantar*—we refer to homeopathy.

From this time on therapeutics gave rise to specialism. Mesmer's successes tempted certain practitioners, who carefully sought among forgotten medications for those that might lend themselves to greater development and a more complete systematization; thus were created hypnotism, metallotherapy, electrotherapy, gymnastics, hydrotherapy and many others which were brought to a high degree of perfection. Then came the great discovery of general anesthesia by ether made by Morton in 1846, while a year later Simpson discovered the anesthetic use of chloroform.

ANESTHESIA

As the story of the first use of ether has often been incorrectly reported, perhaps I may be excused if I give the true facts in detail. These facts are taken from the biographical notes of John Collins Warren of Boston (*The Life of John Collins Warren, M.D.*, by Edward Warren, M.D., Boston, 1860). The first operation under the influence of ether was performed on October 16, 1846.

"The introduction of ether into surgical operations was done by my hands. Mr. W. T. G. Morton, a dentist, of Boston, called on me to say he had found the means of preventing pain in surgical operations, and he was so sanguine in regard to his new application, that I agreed to employ it on the first opportunity.

"The prevention of pain in surgical operations had been a subject I had discussed almost annually in my lectures. I had tried many experiments myself, and had allowed mesmerites and magnetizers to make their trials.

"Nothing, however, had the desired effect, in any degree, but opium; and in cases which threatened to be very painful, as in a case of lithotomy, if I saw no objection, I was in the habit of giving to grown males eight or ten grains, with some degree of effect in obtunding the pain.

"The use of ether, after a few trials, became quite satisfactory; and, from that time, few surgical operations were performed in Boston without it. Many hundred operations have been done by Dr. Mason Warren and myself with ether; and, considering the great power of this agent, it is wonderful we are able to say, that no important ill consequence at any time has occurred.

"A little more than a year after the introduction of ether, Dr. Simpson, of Edinburgh, unluckily introduced chloroform as a substitute. Chloroform was already known to chemists, and had been used as an anesthetic by Mr. Bell, of London, the previous summer. Soon after, a series of deaths from this substance began to take place, and continued, till, in about two years, twenty deaths had occurred. Having previously published *Ether, with Surgical Remarks*, containing an account of ether, and of a number of surgical cases and new operations in which it had been happily employed, I felt myself bound to show the dangerous effects of chloroform, and

to warn surgeons against the use of it. Moreover, I thought it best to recommend ether in the place of it, or, what I particularly preferred, 'strong chloric ether,' which I had directed to be prepared as a substitute. This is preferable to the other, with the exception that it makes the face smart; an inconvenience which can be avoided by rubbing the face with ointment.

"The first publication I ever made on ether was a newspaper article, soon after its introduction. I also wrote letters to the South, recommending it; and to the *British and Foreign Medical Review,* in London, and the *Paris Medical Gazette.* In the latter part of 1847, I published *Etherization, with Surgical Remarks;* and, in the year after, objections to chloroform (effects of chloroform and strong chloric ether as narcotic agents). I should also mention, that, as much as forty years ago, I recommended and employed sulphuric ether in alleviating the last pains, particularly from pulmonary diseases. In such a way, I employed it for Thomas Davis, Esq., at that time Treasurer of the State; also for my sister, Mrs. Brown, to relieve pain.

"About two years before Morton made his application to me, Dr. Wells, of Connecticut, applied for leave to introduce the nitrous oxide, or exhilarating gas, in the Massachusetts Medical College. I agreed to it; and he made the trial, but not with such success as to command attention. I have seen it used, however, since, with a decided anesthetic effect. But it is not so convenient as ether, and not so safe; for it prevents the oxygenation of the blood to an alarming degree.

"It was not until some time after I had used ether, that, in a conversation between Dr. Charles T. Jackson, Dr. Gould and myself, I learned that it was on the suggestion of Dr. Jackson that Mr. Morton was first led to use ether to prevent pain. A violent controversy subsequently took place between Jackson and Morton, and I was frequently appealed to for evidence on the subject. The amount of what I know may be comprised in a few words. Jackson suggested the use of ether to Morton, and Morton first employed it to prevent pain in the extraction of teeth; and, at his request, I first used it in a surgical operation. Dr. Jackson has also stated to me, that he advised Mr. Morton to apply to me to use it in a surgical operation."

SUBCUTANEOUS MEDICATION

In 1845 Rynd invented the subcutaneous method of introducing drugs into the organism, a method popularized by Pravaz, which rendered incalculable service to Empirical therapeutics.

In 1866 Guérin invented absorbent cotton dressings, which, to a certain extent, formed a barrier to infection, while two years later the great Lister gave to the world his methods of antisepsis, for the immortal Pasteur had already shown that infection was due to bacterial invasion. The discoveries of Pasteur completely resurrected surgery and transformed therapeutics. By the discovery of specific bacteria Pasteur created pathogenesis and by experimenting with attenuated virus he founded pathogenic therapeutics. From this time on Empiricism has taken a secondary place in the healing art, while pathogenic therapeutics with their pharmacotherapy, with serotherapy and opotherapy are developing every day to the great benefit of humanity.

That great mind of the Renaissance, whose satirical writings had a profound psychical influence on the reform of medicine, religion and law in the years to follow—we refer to Francois Rabelais—has said that the practice of medicine is but a farce played by three actors: the physician, the patient and the disease.

The Temple of Æsculapius at Epidaurus.—Professor Vaquez in an address delivered before a recent conference of the *Amis de la Faculté* described the Temple of Æsculapius at Epidaurus, which was a kind of cradle where medicine began to prattle before it was even conscious of itself. We quote his words: The Æsclepion of Epidaurus was built about the sixth century before Christ; it attained its splendor about the fourth. Thanks to the generosity of the faithful, its buildings were multiplied, and a theatre was built which, if not the largest, was at least the most beautiful in Greece. In 167 B.C. the whole was still standing. Livy and Polybius have given us a most enthusiastic description of this sanctuary, but it was destroyed in 86 by Sylla and pillaged by Silician pirates. Reconstructed about the eleventh century of our era, it resumed all its magnificence thanks to Antoninus the Good, Emperor of Rome, who had new temples built. It was in this state when Pausanias saw it. It survived for a long time the attacks of Christianity and in the fourth century St. Jerome was dumfounded to see his contemporaries still believing in Æsculapius. In 395 the sanctuary was again despoiled by the Goths who under Alaric I devastated the Peloponnesus. But it was not until 426 that the worship of the god was forbidden by a decree of Theodosius II, Emperor of Byzantium.

Have the temples of Æsculapius, particularly this one of Epidaurus, played a part in the evolution of medicine? This is perhaps the most important question left for us to consider. In the opinion of certain authors, Malgaigne, Daremberg, this part amounted to nothing, and the priests of Æsculapius were no more than jugglers and charlatans abusing the sick by means of the grossest superstitions. This is a very severe condemnation against which writers better informed have protested, in particular Littré whose opinion is worth considering. In order to reconcile these two contradictory opinions, it is necessary to consider the two epochs during which the cult of Æsculapius was in vogue. In the fourth and fifth centuries before our era the ancients believed sincerely in the existence and power of their gods; they thought that good and evil came from them and that they were the dispensers of health. The priests were also sincere and tried to find in the dreams of those consulting them the meanings that it was necessary for them to embody in their prescriptions. Also in this remote time medicine was almost exclusively theurgic. Later credulity was dulled, suggestive influence became more difficult, the number of cures diminished, and the priests realized the necessity of having recourse to other methods. They found it in medicine. Interested in curing their sick, they took advantage of the real notoriety that certain lay doctors had attained.—Translated from *Æsculape.*

A SOCIOLOGIST DISCUSSES EUGENICS

Although most of the recognized exponents of eugenics are, naturally, biologists, as a human ecologist, the sociologist is probably better fitted to judge the social value of proposed programs of race improvement. Such is the contention of Professor Warren S. Thompson, of Miami University, in a paper read before a meeting of the American Sociological Society and published in a recent issue of the *Monthly Labor Review*. The eugenics offensive now under way, he finds, rests on three main assumptions that the ecologist has a right to challenge: first, that human nature can be identified with hereditary traits and is therefore unchangeable; second, that we can by means of intelligence tests and by watching their attainment of economic success, pick out the superior people in the population; third, that the processes of human selection are now artificial as contrasted with those existing previous to the last century or two, which were natural; the latter were eugenic, the present ones are dysgenic.

Professor Thompson argues in refutation of the first assumption that the whole of sociology is a challenge to it, for the eugenist fails to understand what social attitudes are and the processes by which they are developed. As to the third assumption, he refuses to admit that the selection of today is less natural than it was two thousand years ago. "It is probably somewhat less rigorous because of modern medicine and charity, but if the lower classes and particularly the defective benefit most from modern charity, the upper classes benefit most from modern medicine, and probably the unfit thus kept alive do not materially change the relative proportions surviving in these different classes. It is the differential birth rate which changes these proportions, as anyone can readily see who studies mortality and natality tables."

It is Thompson's discussion of the second assumption—the significance of intelligence testing and of economic success—that will tend to incite considerable controversy and opposition. A criticism of the present day intelligence tests is that, when there is a high degree of correlation between a high score, good social status, and good schooling, it is assumed that the native intelligence is much higher in these higher social groups, not that the tests, in part at least, by their very nature show up the social factors and assets in the lives of those tested; they are not purely intelligence tests. Also, the tests apply only to native ability of a highly specialized sort—the ability to get on under our present educational system—and not to general ability or intelligence, as is usually assumed. They were devised to select men for the army who could be quickly educated to perform certain given tasks. Finally, the results of the army tests, as set forth by the actual data, do not seem to indicate that those with the highest scores are real superiors, fit for the carrying on and improvement of civilization.

The second part of the assumption—that attainment of a position in the upper economic classes is a proof of superior capacity—depends for its validity upon the possession by these classes of certain specialized faculties, just as the attainment of a high score in the intelligence tests is dependent upon the possession of certain specialized endowments. "One is disposed to wonder whether, unconsciously, the intelligence tests have not been devised to pick out those likely to succeed in the economic competition of our existing social system."

Professor Thompson believes that the qualities enabling people to adapt themselves to the present social process are the following. First, mental alertness is certainly necessary to attain membership in the upper economic classes. But in how many directions does it apply? "Many men of great economic attainment seem almost impervious to new ideas and are quite lacking in that sympathetic imagination which would enable them to understand and appreciate the situations in which other people find themselves." Also they often show a most surprising ignorance of the forces that have brought them to the fore. A second quality is surely tenacity of purpose. But how often does this degenerate into mere obsession, and a thick skinned imperviousness to all but selfish and individual ends—surely not superior but definitely antisocial characteristics. Adaptability is a third characteristic of the economically successful. "The failure to raise children and the failure to modify the social system so that families are not an unnecessary burden, shows a great lack of adaptability in the upper classes, for they control the system. . . . In the face of these considerations, I do not believe we can blithely assume the superiority of the upper classes as a whole and base a sound eugenic program on this assumption."

He concludes with the proposal of a twofold program for the improvement of the quality of population: first, as the eugenists repeatedly urge, elimination of those proved defective from participation in creating the social order; second, change in the present social system so that the raising of a fairsized

family by the members of all classes, except the defective, will not be penalized as at present; and that all children have opportunities to develop their natural capacities.

ICONOCLASTIC

A recently written book by Dr. Abraham Myerson ought to set us thinking [*The Inheritance of Mental Diseases,* Williams and Wilkins, Baltimore, 1925]. The text of the author's discourse is to be found in Francis Bacon, and since it is a lengthy one we should like to quote it merely in part: "But the idols of the market place are the most troublesome of all; idols which have crept into the understanding through the alliances of words and names. . . . The idols imposed by words on the understanding are of two kinds. They are either names of things which do not exist . . . or they are names of things which exist, but yet confused and ill defined, and hastily and irregularly derived from the realities."

It is the term insanity to which Dr. Myerson finds his text applies "with extraordinary emphasis." It is to this already tottering concept that he deals his first iconoclastic blows. Its hold, however, upon the general mind, professional and lay, is attested by the pertinacity with which it resists attack and even, as the author frankly admits, creeps back into his own text. Nevertheless, he justifies a certain amount of inevitable capitulation with common usage if one is candid with oneself and others. He fearlessly exposes this and certain other concepts, the meaninglessness of their unconsidered and therefore unclear definitions, the "fantastic suppositions"—Bacon again—on which they are based. He adduces much actual matter from careful clinical observation and thus points the way to a more accurate nomenclature. Facts can be obtained and terms used less dogmatically only when the realities are more definitely under the eye.

Insanity may have a function in legally and conveniently — however unilluminatingly — designating social responsibility or irresponsibility. But it should no longer be permitted to obscure a mass of facts which have widely different bearings and pertain to conditions in nature, source, and form of manifestation to which, as a term, it gives no clue. Turning directly toward these facts, the writer shows that serious mental dsiease may exist with no insanity present at all.

Mental disease itself is a much abused concept and psychiatry defined as the science of such diseases is quite inaccurately limited. General paresis, for example, surely a disorder in the province of psychiatry, is first of all a disease of the body, quite definitely so. Mental symptoms stand prominently among its manifestations, that is all; a statement which may be made of other diseases. Furthermore, there are numerous mental disorders which never reach a state of insanity. All of which calls for discriminating investigation amid the great variety both of mental and physical phenomena, which may be coincident but cannot justly be grouped under one misleading heading or referred to one underlying condition.

Here the idol of heredity is subjected to the severest thrusts. Biologists, our author objects, have guarded this concept as an abstraction, thus preventing its functioning. Mendelism is apparently a well-established fact; at least it has rendered true service as an hypothesis. Wouldbe Mendelians, and it is American scientists whom Dr. Myerson charges most heavily, have, in its name, applied unscientifically collected data to prove what they first assume. Their acceptance of mental diseases as "really hereditary characters, in the sense that stature and blue eyes are hereditary characters," Myerson believes incompatible with facts. He exposes the irregularly constructed support upon which they find neuropathic constitution behind every form of disorder. They trace this hither and thither so that everything from eccentricity to "softening of the brain" is found to exist in some ancestor or relative to attest the tainted heredity sure to break forth in some one of the polymorphic manifestations at its disposal.

The author does not deny heredity, but he would have the idolatrous trappings removed so that this hypothesis could function in a genuine investigation of exactly what transmission of mental diseases means. Most of such diseases have environmental causes, some unquestionably specific, operating upon the individual or the germ cell. The injury produced may continue to affect the germ plasm for more than one generation and in more than one direction. The results of the injury may grow more intense until the stock is finally destroyed; just as, probably, it tends to grow less until the stock is again in health. Here is the field for a research beyond the abstractions which either deny reality or obscure it.

Incidentally but forcibly Myerson challenges the manner of the socalled investigation and the long accepted account of the notorious Kallikak family. He confesses to a feeling of shame in the face of the unauthentically assembled material so unquestioningly set down and believed far and wide concerning a "nameless feeble minded girl." He expresses disapproval of the complete ignoring of the long line of descendants of Martin Kallikak after he had properly married. He even submits a question modestly suggested by one of his girl students: After all, was

it Martin Kallikak or some one else mating with the nameless girl who started this long line of degenerates?

EXPLOITATION OF IMMIGRANTS

The full text of the report of the Joint Legislative Committee on the Exploitation of Immigrants has recently been published as Legislative Document 76 of the State of New York. A brief quotation from the close of the second chapter of the report, dealing with general conditions, will serve to show why such an investigation was undertaken.

"The testimony of witnesses before the committee reveals that the immigrant coming to this country is frequently exploited and defrauded from 'Ellis Island to the grave,' as one witness graphically stated. From the moment he leaves Ellis Island, he becomes a prey to taxicab drivers, porters and hotel runners, who by various devices endeavor to fleece him of the small savings which he brings to this country. When he seeks employment, through employment agencies, he is cheated either in the fee exacted, or in being sent to distant localities in the elusive hope of securing employment. When in the course of events he accumulates a little money and is desirous of bringing to this country relatives from abroad, he is fleeced by the transmission agent and the steamship ticket agent. When he seeks to acquire a home, he is lured into the purchase of worthless land, sometimes land under water. When he accumulates a little money which he desires to invest, he is induced to purchase foreign money or foreign exchange, frequently on a falling market and on the installment plan, so that long before the last installment is paid the exchange has greatly depreciated or has become worthless. When he or a member of his family becomes ill, he is defrauded by quack medical institutions which advertise to effect immediate cures. When he dies, his family is subjected to extortionate charges for the funeral ceremony, which absorb his savings and leave the widow and children dependent upon the welfare board. Even before the immigrant comes to this country he is systematically forewarned that in his dealings here he should avoid American contact. It is a remarkable fact that nearly all the fraud brought to the attention of the committee was perpetrated on the immigrant by his fellow countrymen."

In scope the investigation included the following subjects: money transmission, notaries public, transportation, and medical practices. It will be of interest here to outline the findings in the last.

Dr. Antonio Stella, chairman of the committee on civic policy of the county medical society of New York, was chairman of the medical committee of the advisory council of the investigating committee, and the report on this phase of the subject consists largely of his testimony and of witnesses produced by him. The doctor's testimony related largely to investigations made by him of advertisements in the foreign language press claiming to effect cures of incurable maladies, or speedily to alleviate physical conditions that can be alleviated only after long, careful and scientific medical treatment. This testimony revealed that there are in this country as a whole about two thousand foreign language newspapers and magazines, with a reading population of about eight million. These publications appear in thirty-two different languages. Stella testified that, judging from his experience, he has found that the majority of immigrant foreigners are dependent on their physical health for their livelihood, and so respond more quickly to quack advertisements, and seek the advice of charlatans rather than that of legitimate physicians. These quacks generally have in their offices interpreters speaking all the languages of the neighborhood. Dr. Stella said: "Fear is the psychological element on which they work. They never attempt to make a real diagnosis, but generally have at hand an x ray apparatus, and the scheme is to show the hand of the patient before the x ray, and ask the relative to see the bones, saying, 'Here, just the same as you see the bones of that hand, I am looking inside of you, and I can see all sorts of worms crawling in you and eating up your insides.' In this way these people are impressed with a terrific fear, and, of course, the point is to extract an amount of dollars in proportion to their fear. . . . The diseases most favored are those of a protracted course, such as tuberculosis, syphilis, cancer, or anything that takes years to cure, even by the legitimate physician. . . . The scheme of these medical quacks is never to charge per visit for an office visit, but for the whole treatment, so the figures for the treatment run very high."

One poor woman testified that she had been required to pay $350, the whole of the life savings of herself and her husband, for stomach treatment before any treatment was given. Stella said that these quack institutions are usually located in impressive quarters, equipped with seemingly elaborate apparatus, and swarming with "doctors" and "nurses" garbed in white. The fake diagnosis of the case is conducted with great elaboration of detail, so that the patient thinks his condition must be very serious. The result is that he is ready to part with almost any sum asked for, and the amount demanded is usually the limit of his resources, which the fake practitioners are very clever at estimating before he leaves the office. In addition to attempting impossible cures, these institutions systematically treat patients for trivial ailments through falsely diagnos-

ing them as serious, then send out the "cured" patient as a propagandist for the "cure."

Stella stated that he believed that if the quack advertisements in the papers could be suppressed, the chain between the charlatan and at least two-thirds of his victims would be broken. He said that attempts had been made by county medical societies and other organizations to induce the publishers of these journals to desist from including quack advertising, but that these efforts had been unavailing because of the vast revenue derived from this source.

He urged that some method be devised for revoking the certificate of authority of the quack doctors who practice through such institutions, and made the suggestion that, if practicable, a statute be enacted whereby medical advertisements, either in the English or foreign press, be viséd by a proper authority before publication, so that deception and fraud might be prevented.

MORTALITY STATISTICS FOR 1921

The Bureau of the Census in its report on mortality statistics for 1921 furnishes some very interesting data. The registration area for that year included thirty-four states, the District of Columbia, and sixteen cities in nonregistration states. There is space here only for a few of the most important figures shown in the report.

The total number of deaths returned from the registration area of the United States, exclusive of Hawaii, was 1,032,009. This amounts to a death rate of 11.6 per 1,000 population, based on an estimated midyear population of 88,667,602, or 82.2 per cent. of the total estimated population of the United States. The rate for 1921, the report states, is much lower than that for any year since the publication of the annual reports beginning in 1900.

The 1,032,009 deaths in the registration area, exclusive of Hawaii, are distributed between the sexes and between white and colored as follows: Males, 52.8 per cent.; females, 47.2 per cent.; white, 88.2 per cent.; colored, 11.8 per cent. Of the colored, the great majority, 96.3 per cent. (equivalent to 11.3 per cent. of the total for all races) are negroes.

The age tables show a remarkable decrease in deaths of infants and young children, due probably to health education and the resultant better care which children now receive in the home. The figures are as follows: In 1900 the deaths under one year of age formed 20.7 per cent., and those of children under five 30.4 per cent. of the total deaths at all ages. In 1921, the corresponding percentages are 15.5 and 21.4.

The highest annual rate from all causes in 1921, by month of death, is for February (13); this rate is 11.8 lower than the corresponding rate (24.8) in 1920, the decrease being due to the great reduction in deaths from influenza and pneumonia. The lowest rate (10.6) is for September. The only months showing slight increases are July, August, and October.

MORTALITY IN NEW YORK STATE

According to the New York State *Weekly Bulletin*, during 1924 there were in the State, exclusive of New York City, a total of 68,341 deaths, giving a death rate of 14.1 in 1,000. The rate was 0.7 lower than the corresponding rate for 1923, which was 14.8, and 0.4 lower than the five year average for 1919-23 of 14.5. Only one year, 13.7 in 1921, has shown a lower rate. With the exception of deaths at sixty-five years of age and over, which, although decreasing over the corresponding total for 1923, increased by 1,000 over that of the five year average, general decreases in other age groups were indicated.

Deaths under one year of age were lower than those of any preceding year and 1,127 less than those of the preceding five year average, which was 8,414. The infant mortality rate was 71 in 1924, 79 in 1923, and 83 in 1919-23. Contributing largely to the reduction in number of the deaths under one year over those of 1920-23 were acute respiratory diseases, gastrointestinal diseases, premature birth, and congenital debility. The death rate from diarrhea and enteritis under two years of age declined 40.2 per cent. over that of 1919-23. Of the important epidemic diseases, whooping cough and acute anterior poliomyelitis are the only causes recording increases over the five year average. Of the diseases common to adult life there was increased mortality from cancer, cerebral hemorrhage, acute and chronic nephritis, and organic heart diseases. Deaths from external violence also increased. Automobile fatalities continued to hold their position as the highest contributing factor to the increasing number of deaths from accidental causes, the rate for 1924 of 21.1 per 100,000 population showing an increase of 4.0 over the five year average.

News Items.

Military Surgeons to Meet.—This organization will hold its annual meeting at the Waldorf-Astoria, New York, October 8th to 10th.

American Public Health Association.—This society will hold its fifty-fourth annual meeting at St. Louis, October 19th to 22d. Programs of special interest to the medical profession will be on public health, epidemiology, industrial hygiene, mental hygiene, child hygiene, and health education.

Tuberculosis Survey.—The Boston Tuberculosis Association will conduct a survey of the city as a basis for a more extensive antituberculosis campaign. The study will be done through the cooperation of various health agencies, and will be under the direction of Murray P. Horwood, Ph.D., of the Massachusetts Institute of Technology.

Free State Medical Regulations.—The Government of Irish Free State announces that subject to ratification by the Irish Parliament, it will establish a separate and independent medical register, beginning next February. This will bar doctors qualifying in the Free State from practice in Great Britain or northern Ireland, and doctors from those sections from practice in Ireland.

American College of Surgeons.—The next clinical congress of the American College of Surgeons will be held at Philadelphia, from October 27th to 30th. Sir Arbuthnot Lane of London will deliver the Murphy Oration on Surgery, and the Fellowship Address will be given by Lord Dawson of London; the president-elect, Dr. Rudolph Matas, of New Orleans, will give the inaugural address. A hospital conference Monday and Tuesday will be held in connection with the congress.

Gifts and Bequests.—The will of Mrs. Dorcas Knox Braisted of New York leaves her residuary estate, worth around a half million dollars, to be divided equally among seven charitable organizations, which include the Manhattan Eye, Ear and Throat Hospital, the White Plains Hospital, and the Northern Westchester Hospital; $20,000 also was given to the Northern Westchester Hospital Association of Mount Kisco.

The will of the late Wilson Catherwood provides $250,000 for the Children's Hospital of Philadelphia, and $50,000 for the Pennsylvania Hospital.

The will of the late John H. Flagler provides $365,000 for St. Luke's Hospital, New York, and $265,000 each to New York and Presbyterian Hospitals. The sum of $400,000 will establish the Alice Mandelick Flagler Foundation, which is chiefly for nurses' homes.

The will of the late Henry H. Jacobson provides $1,000 each for Mount Sinai and Montefiore Hospitals.

St. Rose's and St. Francis' Hospital each receive $5,000 from the will of the late Maria Monica MacSloy, the balance of her estate going to St. Vincent's.

Under the will of Albert H. Whipple, of Whitinsville, Mass., the Whitinsville Hospital will receive $2,000 on the death of the testator's wife.

The Union Hospital Association will receive $162,000 and the Beth David Hospital, $81,000, from the will of the late John J. McKenna.

The New York Eye and Ear Infirmary will receive approximately $50,000 from the will of the late Dr. Nicholas R. Dann.

Col. Henry H. Rogers has given $30,000 to the Southampton, Long Island, Hospital, which will provide for an addition to the school of nursing, and for its physiotherapy work.

THE REPORT OF THE SUBCOMMITTEE ON THE CONVALESCENT CARE OF MEDICAL PATIENTS OF THE PUBLIC HEALTH COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE

(*Concluded from page 297*)

HOMES FOR SPECIAL TYPES OF PATIENTS

Provision should be made, either through special homes or through special departments of a large convalescent home, for meeting the requirements for convalescence of certain types of patients. These types are the cardiovascular, the dietetic and the respiratory.

Cardiovascular group.—Whether convalescent from active heart disease or from heart failure these patients need supervision and a regimen somewhat different from other convalescents. Convalescent homes undertaking the care of cardiac patients should be situated preferably in a rural district, not at the seaside, and at not above 1200 feet altitude. Patients should not be required to live above the second floor unless elevators are provided.

The medical care of the patients should be under the control of one or more consulting physicians who should visit the convalescent home at intervals and see that the medical regimen is properly carried out. A physician trained in the management of heart disease should either be resident in the institution or visit it each day. He should examine each patient on admission and on discharge and make other examinations at regular intervals. He should prescribe the amount of rest and exercise that each patient is allowed. In large homes patients should be arranged in groups, such groups being made up of patients allowed similar amounts of rest and exercise. There should be a physical director who should have charge of the exercise and recreation of the patients the amount and character of which, however, shall be determined by the physician.

Dietetic group.—One or more visiting physicians should be appointed for these institutions. Competent dietitians will be required for these cases though one less carefully trained may be assigned for the alimentary group of patients. Limited laboratory facilities should be provided where diabetic patients may be taught to make the necessary examinations of their urine. This should be a useful adjunct in the case of other groups.

Respiratory group.—In homes for these patients somewhat more than the usual amount in cubic feet of air per bed should be provided. The danger of infection should be considered and patients recovering from infectious conditions should be segregated as to their sleeping accommodation. They need not be excluded from the common dining room if mechanical dishwashing apparatus which sterilizes is used. Opportunities should be provided for outdoor life in cold or bad weather for those who would be benefited by it and the daily routine should be adapted to this purpose.

As the requirements for patients recovering from respiratory conditions are almost entirely limited to about six months in the year, some arrangement which would utilize these homes as vacation homes during the summer months is recommended.

THE STAFF OF THE CONVALESCENT HOME

The subject of the care and management of the convalescent state in homes specially organized for that purpose has an educational aspect. In the first place the patients themselves, even in the short time of their residence in a home of this nature, will learn how to correct errors in personal hygiene and faulty habits of living. They gain also a knowledge of the causes, preventable in many cases, that have brought about the condition from which they have suffered. This knowledge will be the more readily attained and be the more firmly fixed if it be imparted with intelligence and tact on the part of those in whose care they are for the time being. And so this had considerable bearing upon the problem of the appointment of proper personnel on the staff. Furthermore, as the question of convalescence is studied, it will bring out many matters of educational value to the individual members of the staff also.

Any group of convalescent patients requires medical supervision, and an institution, even of the simplest kind, should make provision for this, either by maintaining a resident physician or by arrangement with one of the physicians in the vicinity for stated visits; several homes conveniently situated may combine in such arrangement. In a convalescent home which is restricted to patients of one type a resident physician is especially needed, and one who has had special training in the type of disease under care is to be preferred.

It would be advantageous if some plan could be formed for a visiting staff of consulting physicians

whereby the homes can be coordinated with the staff of hospitals whence the patients come. This can best be worked out after the homes are established.

The resident physician should be appointed for a definite but limited term of service and should be paid a salary. The character of the service in some of the homes would probably not be especially attractive, so that oftentimes it would be difficult to obtain a physician well fitted for the position. In the special type of homes, on the other hand, for example, the home for cardiac patients, there should be unusual opportunity for study, and the position of resident should have a strong appeal. Women physicians, in particular, might find a favorable field of work in this position.

The resident physician should have authority over the nursing staff and the dietitian and physical director should be responsible to him.

Every convalescent home should have a competent, fully trained nurse in charge; other nurses or trained attendants in subordinate positions should be appointed by her.

A competent dietitian should be one of the staff of homes for convalescents requiring dietary supervision. Homes with no dietitian will need a housekeeper with knowledge of diets and the proper preparation of food.

There should be a physical director having charge of all physical activities of the patients. The physician, however, should prescribe the kind and amount of exercise suited to the patients.

THE EQUIPMENT OF THE CONVALESCENT HOME

In every convalescent home there should be simple equipment for physical exercises and apparatus necessary for indoor and outdoor games and other forms of amusement. The ordinary equipment for the examination of patients is to be provided, including medical scales for the weighing of patients, a few remedies, simple surgical dressings and instruments, and antidotes for poisons; and laboratory facilities for the examination of urine.

It is essential that there be a room set apart for the prompt isolation of a patient should occasion arise, as it may in any convalescent home.

The special equipment necessary in a home for heart cases includes a sphygmomanometer, a spirometer and a standardized preparation of digitalis; in a home for the care of diabetic patients a laboratory where patients may make examinations of urine is needed, and in homes for respiratory convalescents a sufficient number of atomizers and inhalation apparatus for individual use and individual equipment for outdoors in cold or wet weather.

RECORD SYSTEM

In a convalescent home there should be kept a proper record of each patient. In the record should be the findings of physical examinations, a chart of weight, and general improvement, a statement of the treatment prescribed and an account of any interruption of a steady convalescence. In special homes, cardiac and dietetic particularly, the record should be more elaborate and contain such additional data as may be of aid in furthering scientific knowledge of the disease from which the patient suffered.

CENTRAL BUREAU AND FOLLOWUP SYSTEM

For the proper placing of convalescent patients there should be a central bureau or clearing house organized by the homes themselves. This requires an office in the city with a small personnel. In this central office would be kept a list and description of convalescent homes and a census record of the number of vacant beds available. Hospitals, dispensaries or physicians would file applications for admissions to convalescent homes, with necessary data concerning the applicant. The central bureau would then select the proper home and arrange for the transportation of the patient. The bureau would see also that with each patient there was sent an adequate record, including examination diagnosis, duration of disease and treatment given. A standard form should be used for this information in order that it may be incorporated directly into the records of the home. On final discharge of the patient the home should forward to the place from which the patient was sent a statement of the length of stay in the home and of the condition on discharge.

CONCLUSION

The management of convalescence is of great importance in that this determines the time and the completeness of a return to health and thus resumption of work. Convalescence should be considered as a stage in an illness and not as a dissociated event. Adequate measures, therefore, should be employed to insure proper treatment during the convalescent state.

At the present time convalescent management is unsatisfactory. The homes in existence are not correlated, the organization in general is not a comprehensive one and the supply of convalescent beds is far below the normal demands.

Two classes of convalescent homes for medical cases should be planned; one for private, hospital and dispensary patients who are able to pay a moderate sum for their maintenance; another for those able to pay little or nothing. Both classes should make provision for adequate care of one or more of the different types of medical convalescents, provisions for quarters, staff and treatment.

The correlation of the homes, their relationship to hospitals, dispensaries and physicians, and the distribution of patients to them, should be in charge of a central agency.

A comprehensive plan for convalescent relief should begin with the establishment of this central agency and the classification and where necessary, the reorganization of existing homes. With this accomplished, the further development should be along lines suggested in this report.

PNEUMONIA

Pneumonia. Its Pathology, Diagnosis and Treatment. By the Late R. Murray Leslie, M.A., B.Sc., M.D. Edited and Revised by J. Browning Alexander, M.D., M.R.C.P. (Lond.) London: William Heinemann (Medical Books) Limited, 1924. Pp. 351.

This monograph is the result of an attempt to give the reader a succinct account of all that is known about pneumonia from the earliest days to the present time. The original author, R. Murray Leslie, gives his wide experiences with diseases of the chest over a period of almost thirty years. It is a posthumous work, and the only part of the book that needed revision was that dealing with bacteriological questions, such as the typing of the pneumococcus according to the Rockefeller Institute classification. There was also too much enthusiasm regarding the value of vaccine therapy at the time of the original writing and, therefore, the opinions on this subject had to be modified somewhat.

The introductory chapter outlines the history, nature, incidence, epidemiology and classification of pneumonia. Thirteen chapters are devoted to the etiology, pathology, clinical features, symptomatology, physical signs, atypical forms, complications and sequelæ, diagnosis, prognosis, prophylaxis and the treatment of lobar pneumonia. Special chapters, respectively, are devoted to bronchopneumonia, influenzal pneumonia, pneumonia in children, surgical (postoperative) pneumonia, socalled specific drug treatment, specific serum therapy (antitoxin treatment) and specific vaccine therapy. Good results are reported from the intravenous injection of hydrogen peroxide in a series of cases of severe influenzal bronchopneumonia—a procedure rarely used in this country.

Taken by and large, this book may well be recommended as a safe guide in the treatment of pneumonia. The reasons for each therapeutic indication are clearly given. The style is intensely didactic and makes interesting reading. The bibliography is quite extensive and includes references not only to English, but also to American and German literature. It is a most complete treatise on the subject of pneumonia.

CRIMINAL ABORTION

Die Uneheliche Mutterschaft. Eine Sozialgynäkologische Studie, Zugleich ein Beitrag zom Problem der Fruchtabtreibung. Von Dr. Egon Weinzierl. Mit 4 Kurven und 10 Tabellen im Text. Berlin-Wien: Urban & Schwarzenberg, 1925.

The subject of criminal abortion and the mitigation of the evils resulting therefrom is now receiving world wide attention. In this monograph the author strikes at the root of the causes of abortion. He systematically investigates the various motives that induce mothers to subject themselves to this procedure. This subject is of momentous interest not only to physicians and surgeons, but also to lawyers, sociologists, hygienists, theologians, moral philosophers and statesmen. It is also quite an important part of state politics, social hygiene and race biology. Its large contribution to mortality, morbidity and sterility makes it of great practical importance; it affects not only the individual woman, but also the family and the entire state.

The causes of the recent rapid increase in criminal abortion are to be sought chiefly in the changes in moral concepts and the unfavorable economic conditions, increased especially as a result of the World War. The various measures proposed heretofore to meet this problem include the repeal of laws punishing the perpetration of abortion, the repeal of the laws favoring professional secrecy, the introduction of laws for the official reporting of abortions by physicians and midwives, the eradication of quackery, the supervision of midwives and the prohibition of contraceptives.

Abortions are much more common in married than in unmarried women. The author conducted a systematic and minute investigation on his material of five hundred unmarried females as to the reason for their resort to abortion and also as to their reason for their desire to complete their pregnancy. The social and mental status of each mother and father were also carefully studied.

The following recommendations are made: 1, elevation of the psychic level and moral attitude of young women by educational means; 2, the development of social welfare agencies, and 3, the promulgation of new laws for the official reporting of every pregnancy and abortion and the establishment of a set of rules for the indications for the interruption of pregnancy. These measures the author believes will help considerably in the production of socalled desired children.

This is a very comprehensive review of the whole subject of unmarried motherhood and criminal abortion well worth reading.

REPORT OF THE TRUDEAU SANATORIUM

The Fortieth Annual Medical Report of the Trudeau Sanatorium and of the Trudeau Foundation, 1924.

This is an unusually interesting report and shows the valuable work the sanatorium is doing. The report proper is preceded by an introduction by Dr. Lawrason Brown, and the details are given by the chief resident physician, Dr. Fred H. Heise. The Edward L. Trudeau Foundation for Research and Teaching in Tuberculosis publishes the following interesting studies:

The Value of the Trudeau Sanatorium's Five Diagnostic Criteria of Pulmonary Tuberculosis in Negative Cases. A Study of 264 Cases Admitted to the Sanatorium, Diagnosed as Nontuberculous and Followed Up from One to Seven Years. By Lawrason Brown, M.D., and Fred H. Heise, M.D., Trudeau Sanatorium.

An Attempt to Classify by Means of the X Ray Cases of Suspected and Definite Pulmonary Tuberculosis Showing Less Than a Definite Parenchymatous X Ray Lesion. By Fred H. Heise, M.D., and Homer L. Sampson, Trudeau Sanatorium.

Immunological Studies in Tuberculosis. II. Further Observations on Skin Hypersensitiveness in Experimental Tuberculosis. By S. A. Petroff, Ph.D., Research and Clinical Laboratory, Trudeau Sanatorium.

Studies with Ultraviolet Light. I. The Effect of Quartz Mercury Vapor Irradiations (Alpine Quartz Light) on Experimental Tuberculosis of the Cornea in Rabbits. By Edgar Mayer, M.D., and Morris Dworski, A.B., C.P.H., Saranac Laboratory for the Study of Tuberculosis.

Studies with Ultraviolet Light. II. The Action of Quartz Mercury Vapor Irradiations on Inhalation Tuberculosis in Primarily Infected and Sensitized Guineapigs. By Edgar Mayer, M.D., and Morris Dworski, A.B., C.P.H., Saranac Laboratory for the Study of Tuberculosis.

Studies with Ultraviolet Light. III. The Bactericidal Action of Mercury Quartz Vapor Light Irradiation. By Edgar Mayer, M.D., and Morris Dworski, A.B., C.P.H., Saranac Laboratory for the Study of Tuberculosis.

PHOTOSYNTHESIS

The Physiology of Photosynthesis. By Sir Jagadis Chunder Bose, M.A., D.Sc., LL.D., F.R.S., C.S.I., C.I.E., Director, Bose Research Institute, Calcutta. With sixty illustrations. New York, Toronto, Bombay, Calcutta and Madras: Longmans, Green and Co., 1924. Pp. xx, 287.

In reading this book we avail ourselves of the privilege of applying the interest of the specialist in the field of plant life or of that of the physiologist devoted to the study of human activity. Either student will be stimulated by this carefully prepared account of experiments directed to quantitative investigation of photosynthesis. The writer gives the minute technical steps of his procedure and with these frequent brief summaries of the progress of his experiments. He keeps always in mind the cosmic extent and significance of the phenomenon under examination. Thus the book pertains to the processes of life at whatever level and in whatever form. Photosynthesis is carried on at the physiochemical stage but just as these investigations serve to establish the "underlying unity of physiological mechanism in the plant" so do the author's work and his conclusions remind us of the unity of function and the similarity of its character in all living activity. It is the same life task which is performed in the plant or repeated in more and more complicated form from the lowest to the highest function of the highest organism, man. The process, physicochemical or psychical and conscious, is that which the author has summarized for the plant, "a state of unceasing activity, absorbing and storing energy from without, setting free and dissipating it from within."

TROPICAL MEDICINE

Proceedings of the International Conference on Health Problems in Tropical America. Boston: United Fruit Company, 1924.

This volume of transactions contains an imposing array of contributions, including papers by such well known observers as Rosenau, Bass, Agramonte, Rogers, Noguchi, Castellani, Ashford, Banting, Lane, Newsholme, Oliver, Park, and Deeks, as well as a host of other outstanding workers in tropical diseases. Coming from such sources, the information presented may be said to reflect the very latest knowledge concerning this class of disorders, as well as certain nontropical subjects such as insulin, by Banting; the causation of cancer, by Lane; vaccines in pneumonia, by Park, etc. A very wide range of tropical disorders is covered in this volume, and the results of much experience in their diagnosis and treatment are summarized. Altogether, the book cannot fail to be of absorbing interest to all concerned with the diseases prevalent in hot climates. The editing of the volume, as well as its mechanical features, leave nothing to be desired.

BIOLOGY

Handbuch der biologischen Arbeitsmethoden. Unter Mitarbeit von 500 bedeutenden Fachmännern herausgegeben von Dr. Emil Abderhalden, Direktor des Physiologischen Institutes der Universität Halle a.d. Saale.

Abt. IV, Angewandte chemische und physikalische Methoden, Teil 9, Heft 3. Methoden sur quantitativen Bestimmung des Stoffwechsels des Gesamtorganismus von Organen und Zellen.

J. E. Johansson describes the technic of studying the metabolism of energy. L. Langstein and E. Edelstein describe the technic of obtaining the total metabolism of infants. A. Gigon describes his comparative studies on the metabolism of man on an unselected diet. E. Küster discusses the method of raising of mammals free from bacteria.

Abt. IV, Angewandte chemische und physikalische Methoden, Teil 10, Heft 3. Quantitative Bestimmung des Gasstoffwechsels.

This number is concerned solely with a description of the methods of determining the gaseous metabolism in animals and man, as used at the nutrition laboratory of the Carnegie Institute of Washington. It is a highly technical monograph.

Abt. IV, Angewandte chemische und physikalische Methoden, Teil 12, Heft 2. Gerichtliche Medizin.

E. Ziemke describes the chemical, microscopic and physical methods for the examination of blood from the medicolegal standpoint. It is a very practical, exhaustive and useful monograph on the subject.

Abt. V, Methoden sum Studium der Funktionen der einzelnen Organe der tierischen Organismus, Teil 5A, Heft 2. Methoden der Muskel- und Nervenphysiologie.

R. Grammel gives the theoretical foundations for the mechanics of joints as worked out by higher mathematics. E. Hirt describes graphic methods for the demonstration of normal and pathologic courses of voluntary movements.

Abt. XII, Methoden zur Erforschung der Leistungen von einzelligen Lebewesen, Heft. 3. Spezielle Methoden. Untersuchungen an einzelligen Lebewesen.

E. Pribram and F. Zach describes the most important methods used in working with fungi. These are described in great detail and are of a highly technical character. The same applies to the article by F. Fuhrmann and E. Pribram on the most important methods in the work with bacteria.

Abt. XIII, Methoden der Immunitätsforschung und der experimentellen Therapie, Teil 2, Heft 3. Berlin, Wien: Urben & Schwarzenberg, 1924.

F. v. Gröer discusses skin reactions. The technic of the tests and the clinical features of the reaction are described in great detail. The various reactions are illustrated in colors. Skin reactions are divided into (1) functional skin reactions, (2) inflammatory reactions, and (3) cutaneous pigment reactions. The functional reactions are subdivided into those due to mechanical stimuli, those due to thermic, electrical and actinic stimuli with avoidance from tissue injury, and the pharmacodynamic reaction. The form pro-

duced by mechanical stimuli includes the dermographic reaction and traumatic reaction. The pharmacodynamic reaction may be a lymphagogue reaction, may be due to vasoconstrictor or vasodilator drugs, or there may be a combined vasoconstrictor and vasodilator reaction. The lymphagogue reaction is subdivided into three groups: 1, that due to hypotonic and hypertonic solutions, as various ions and some indifferent crystalloids and colloids; 2, to alkaloids; and 3, to proteins, protein split products and biologic substances.

The inflammatory skin reactions may be classified into three groups: 1, those due to mechanical stimuli; 2, those due to thermic electrical and actinic stimuli; 3, those due to chemical physicochemical and biologic stimuli. The latter may be subdivided into primary and secondary toxic phlogogenic substances. The former may be of known or unknown nature and include the genuine proteins and protein decomposition products.

B. Schick, F. v. Gröer and K. Kassowitz discuss the method and technic of studying the normal antitoxic immunity to diphtheria in man. K. Landstiner describes the methods of making antigens and antibodies for immunochemic investigations.

E. Paschen describes the technic of the microscopical study of the virus of smallpox.

GYNECOLOGY

A Practice of Gynecology. By Henry Jellett, M.D., F.R.C.P.I. Fifth Edition. With 417 Illustrations (Many in Color) and Fifteen Colored Plates. Philadelphia: Lea & Febiger, 1925.

This edition has been considerably revised and amplified. The additions include such subjects as Gas Inflation of the Peritoneal Cavity and of the Fallopian Tubes, Ovarian Transplantation, the Manchester Treatment of Uterine Prolapse, Implantation Adenomata of Endometrial Origin, Sterility, and The General Principles Which Govern Gynecological Operations. The chapter on Menstruation and Its Disorders has been revised to conform with the more modern views as have also the chapters on endometritis and metritis.

Among the list of diagnostic instruments, Hegar's dilators are mentioned. This sounds somewhat obsolete in this country. Barnes's bags are also mentioned but not much used by us. Among us also, it is practically agreed that the curette has no place in the treatment of endometritis, but the author recommends its use.

Menstruation and the menstrual disorders are discussed fully, with emphasis on the endocrines.

The venereal diseases, their prophylaxis, treatment and social significance, are not given the importance they deserve in a book of this kind. Cyllin, a creolin preparation, not much used or known in this country, is recommended in the treatment of gonococcus vaginitis.

Uterine displacement is discussed in profuse detail. The chapters on diseases of the uterus and its appendages are richly illustrated with pictures of the pathological conditions, both gross and microscopic. A special chapter is devoted to injuries due to pregnancy and labor. The charts illustrating the causes of sterility, both in the male and female, simplify the treatment considerably.

The value of vaccine treatment in gynecology, discussed by R. J. Rowlette, is overemphasized. The technic of the preparation and administration of vaccines is given in detail.

W. C. Stevenson discusses radiotherapy in gynecology in a very comprehensive and useful manner.

The latter half of the book is concerned with the surgical anatomy of the genital organs and operative technic. Much space is devoted to the operations for the various types of fistulæ—vesicovaginal, urethral and ureteral—more than is usually devoted to these operations. The illustrations of the various types of operations are well selected and numerous. In regard to ovarian transplantation, the author sees some hope only in the autoplastic grafting of the ovary. The main effect he considers to be the psychic effect. It does, however, defer the symptoms of the menopause and the cessation of menstruation. As much of the ovary as possible should be preserved in situ during operations on the uterine appendages. The Manchester treatment of uterine prolapse, originated by Donald of Manchester, consists of anterior colporrhaphy with excision of the vaginal forni and is recommended as curing all cases of prolapse without the assistance of perineorrhaphy, even if the perineum is badly torn.

The conception of implantation adenomata is a recent one. They result from the implantation of epithelium, which escapes from the fallopian tubes into the pelvic cavity, coming most probably from the lining epithelium of the uterine cavity, or less commonly from the tubes themselves. They are treated either conservatively or radically.

On the whole, the book may be said to be serviceable, especially for medical students.

FICTION

This Mad Ideal. By Floyd Dell. New York: Alfred A. Knopf, 1924. Pp. 246.

Floyd Dell has already distinguished himself as chronicler of the struggle years. Most of his readers have made their painful way across the threshold of adulthood. They can look back with fleeting sympathy on the emotions and ordeals of under twenty-one. And then perhaps if they have read other books by Mr. Dell they will realize that the author feels no such vast chasm separating the young from the mature. Judith and Roy of *This Mad Ideal,* whether with Mr. Dell's consent or not, merely adopt more juvenile phrasing in their wrestling with life.

Judith the girl is supposed to be something of an individual. She quite frequently thinks for herself, but her thinking is nevertheless clouded by the herd. An orphan, she is brought up by well meaning relatives. She is always a little "different" because of that intangible inner life with which Mr. Dell equips her, ostensibly an inheritance from a freeminded mother, or from a shutin period of Judith's life. Dell makes her a moral coward but not a physical coward. His thesis occupies itself chiefly with the outgrowing of her moral cowardice, a function of development in itself. This theme is interestingly handled, contrasted, viewed from all angles. Then put between covers and the job is finished. The question now remains whether that is enough for a novel. Is it enough for Floyd Dell to be better than many and not so good as some? He probably knows.

We hope he considers this a trifling thing, a point on which he must take his stand, get it out of his system to make way for the coping of adult minds with adult situations. He can write interestingly. He can capture that wistful looking back on the comic-pathetic vagaries of youth to perfection. *This Mad Ideal* finds him still looking back. True creative work must look ahead.

Medicoliterary Notes.

During the year 1924 the Health Department of New York City prosecuted in the criminal courts 22,481 cases of violation of sanitary measures.

* * *

Mental Hygiene for April emphasizes the subject of mental hygiene and the college student. The topic is treated by Dr. Frankwood E. Williams in his second article on Mental Hygiene and the College Student; Dr. Arthur H. Ruggles in College Mental Hygiene Problems; Major Harry N. Kerns, M. C., in Management of Acute Mental Hygiene Problems Found Among College Men; and Dr. Martin W. Peck in Mental Examinations of College Men.

* * *

In order to enforce safety in refrigerating plants, a revision of some of the ordinances of New York City has been made which led to the formulation of a code on refrigeration, a classification of the types of refrigerating plants, and safety rules for both.

* * *

A rcent publication of Hoeber is *Pediatrics of the Past,* compiled by John Rurah. It is an anthology of the works of early writers on children's health and care. Other late publications of interest to the medical profession are *The Physiology of Exercise,* by Dr. R. Tait McKenzie (Lea & Febiger); *The Normal Mind,* by Professor W. H. Burnham (Appleton); *Community Dental Service in New York,* a study of the facilities for dental care made by the Committee on Dispensary Development of the United Hospital Fund; *Living Organisms,* by Edwin S. Goodrich (Oxford Press); *Mental Diseases,* by Dr. James V. May (Gorham Press); *Social Consequences of Business Cycles,* by Maurice B. Hexter, Ph.D. (Houghton); and *Health and Environment,* by Leonard Hill, M.B. (Longmans).

* * *

Dr. Louis Casamajor, professor of neurology at Columbia University and visiting neurologist at Beekman Street Hospital, New York City, plans to establish a "morale" clinic which he proposes to make the nucleus of an extensive study of industrial neurosis to find what factors delay return of function in the event of injury. . . . . Dr. Casamajor proposes to make investigation of large industrial plants throughout the country—those where the morale is low and those where it is high—in an endeavor to get at the underlying causes in each case.—*Nation's Health.*

* * *

Good books for Fall week-end outings are *A Mother's Recompense,* by Edith Wharton; *Beau Geste,* by Percival C. Wren; *Bill the Conqueror,* by P. G. Wodehouse; *Stolen Idols,* by E. Phillips Oppenheim; *What of It?* by Ring Lardner; *High Noon,* by Crosbie Garsten; *The Great Gatsby,* by F. Scott Fitzgerald; *The Annexation Society,* by J. S. Fletcher; *Love,* by Elizabeth of German garden fame; *The Glorious Apollo,* by E. Barrington; and the *Cuckoo in the Nest,* by Ben Travers.

* * *

New York State has assigned a quota of $1,000 to every school district employing a medical inspector in full time in an effort to stimulate medical inspection of schools.

* * *

In a pamphlet recently issued by the American Society for the Control of Cancer four ways are given in which the nurse can aid in cancer control. They are as follows: 1, By making herself a source of authentic information with respect to prevention, recognition and cure of cancer; 2, By detecting early cases which would otherwise escape recognition until they had passed to an incurable stage; 3, By exerting an intelligent influence upon those who have cancer in its early and curable stages, and inducing them to seek immediate and competent treatment; 4, By exerting through her enlightened intelligence an influence against the operations of quacks and other incompetent persons who but add to the plight of cancer patients. The booklet adds that the nurse can also render great assistance in combating the unreasoning fear of "the knife." Through her own experience she will be in a position to explain, and so can bring to those with whom she associates a rational view of cancer, its prevention, treatment and cure.

* * *

The National Committee for the Prevention of Blindness has recently issued its tenth annual report. From a small group of sixty-five men and women the membership has grown to 10,053, with representatives from every State in the Union.

* * *

Specialized Courts Dealing With Sex Delinquency is the title of a work recently published by the Bureau of Social Hygiene of New York. The writers are George E. Worthington of the American Social Hygiene Association, and Ruth Topping of the Bureau of Social Hygiene. The book comprises studies of procedure in Chicago, Boston, New York and Philadelphia.

* * *

The number of hospitals in the United States has increased since 1873 from 149 to 6,762; the number of hospital beds in the same period from 35,453 to 770,375; the population of the country has increased during the same years from 38,558,371 to 105,710,620.

* * *

An increasing number of colleges and universities in the United States are offering courses on public health subjects, in their summer schools. These courses last from three to six weeks and in many instances an extensive program is presented, with instruction and lectures by authorities in their various fields. There are more than ninety courses in all.

* * *

The proceedings of the annual meeting in 1924 of the International Association of Industrial Accident Boards and Commissions has recently been issued as *Bulletin* 385 of the Bureau of Labor Statistics.

* * *

In the course of a year, according to a recent report, every American resident consumes on the average more than ninety pounds of pork. The per capita consumption of beef is more than sixty pounds. Veal is only eight pounds per capita, and mutton and lamb only five pounds per year.

* * *

A recent number of the *Manchester Guardian Weekly* gives the following amusing account of a discussion which took place lately when the House of Lords was considering the Performing Animals bill.

Viscount Ullswater said he would like to know whether "animal" included insects. He was not a trainer of fleas, but what would happen under the bill to a man who withheld from fleas their natural food, which he presumed was human flesh? Would he or would he not be treating them with cruelty? Lord Desborough for the Home Office stated "animal" included birds, reptiles and fish. He was sorry that fleas apparently did not come within the scope of the bill.

Viscount Ullswater said that before the report stage had been reached he hoped the noble lord in charge of the bill, Lord Danesfort, would consider whether insects should be included. Lord Danesfort said that until Lord Ullswater spoke he had not realized the great importance of the matter. He would consider it. Lord Desborough added that he wished fleas had been brought to his attention before.

The bill passed through committee.

The *Nation's Health* recently printed in full the prize winning article of Mr. Edward A. Fitzpatrick on Interrelationships of Hospital and Community. A prize contest for articles dealing with this subject was announced by the Modern Hospital Publishing Company. The first prize of $350 was awarded to Mr. Fitzpatrick, who is dean of the Graduate School of Marquette University, Milwaukee, Wis.

Abstracts from Current Literature

ENDOCRINOLOGY

Endocrinology in Pediatrics, With Special Reference to the Hypoplastic Dyspituitary Type of Child.—H. L. Dowd (*Archives of Pediatrics,* December, 1924) states that persons of all ages may be abnormal or inadequate because of glandular deficiencies. Children of the status thymicolymphaticus type, frequently overweight, sometimes tall, slender and loose jointed, are a difficult problem of adjustment. The nature of their growth and development renders them frequently selfconscious, inadequate, prone to injury, and with a low resistance to infection. They can be assisted more rapidly to a condition of normality by a study of their internal secretions, with the administration of the appropriate glandular extracts, than by neglecting these glands and relying entirely upon measures relating to diet and hygiene and correction of physical defects. Even the cretins are not the simple cases of thyroid deficiency that they have always been considered. They are hypoplastic and their trouble is a pluriglandular one. Such conditions as epilepsy have some relation to disturbances of the internal secretions that warrants further study. Pituitary extracts have a distinctly favorable influence on fatigue and on such symptoms as headache and bedwetting when used in proper amounts and can aggravate the condition if an overdose is given.

Caution must be observed in the use of glandular extracts. Thyroid should be used in small doses, while pituitary whole gland and the anterior lobe extracts can be pushed unless headaches ensue which were previously absent, or the existing one is aggravated. In some cases the enuresis will be aggravated rather than improved if too much extract is given. In addition to the administration of these extracts by mouth, they may be given by injection with benefit in selected cases. Ovarian and testicular extracts are useful where puberty is delayed. Large doses of pituitary extract are not indicated when the sella is small and enclosed, or severe headaches will follow. Rest periods when doses are omitted are necessary from time to time.

It is a temptation for a gland enthusiast to believe that altered internal secretions are responsible for all human ailments, but a mean between extremes is possible and many children can be made happier and more efficient by the proper use of glandular extracts. Standard potent products must be used if success and uniform results are to be obtained. As yet there has been very little standardization in proportion to the vast amount of gland extracts produced.

Suppression of Bile as a Result of Impairment of Liver Function.—D. R. Drury and Payton Rous (*Journal of Experimental Medicine,* May, 1925) state that prolonged chloroform anesthesia causes an acute suppression of bile, as shown by the secretion of a thin "while bile" from which bilirubin, cholesterol, and bile salts are absent. The failure of the liver to secrete bilirubin under such circumstances is not due to failure of the pigment to be formed within the body, as an unusual amount is elaborated after chloroform anesthesia because of blood destruction. The evidence goes to show that bile suppression is consequent upon a functional disturbance of the liver, not upon obstruction to outflow. Even uncomplicated biliary obstruction, as when the common duct is tied in animals otherwise normal, causes a disturbance of the liver cells such that their secretory function is impaired, as shown by the inability to take up and secrete sodium indigotate.

Liver Function in Various Diseases as Tested by the Administration of Levulose.—Reuben Finkelstein and Max Dannenberg (*Journal of Laboratory and Clinical Medicine,* April, 1925) performed the levulose test on thirty-eight consecutive patients. No food was given after the evening meal. Next morning the patient, still fasting, blood was taken and the sugar content determined. Fifty gm. of levulose dissolved in water was given. The blood sugar was again determined at half hour intervals for two hours. The blood in cases one to twenty-six was tested by the Benedict method; in cases twenty-seven to thirty-eight by the Epstein method. The positive and negative results are about equally divided. The nineteen cases in which no increase in blood sugar was observed represent fourteen different diseases; the other nineteen cases representing twelve various diseases gave an elevated blood sugar curve for a period of at least two hours. While the series is rather small for the drawing of conclusions, the test was positive in acute and chronic gallbladder infections in five cases; in icterus, in carcinoma of the pancreas, and in chronic passive congestion of the liver (four cases). The curve was also positive in a few other conditions in which there was no other clinical evidence of hepatic injury.

Adrenalin for Manual Separation of the Placenta.—Robert Joachimovits (*Wiener klinische Wochenschrift,* May 8, 1924) recommends the moistening of the sterilized hand with a solution of adrenalin made up by diluting one c. c. of a one tenth of one per cent. solution of adrenalin with four c. c. of sterile water. The purpose of this procedure is to cause an immediate contraction of the bloodvessels. The uterus does not contract at first, but the hemorrhage stops. This contraction of the bloodvessels minimizes the danger of the penetration of bacteria considerably and the immediate hemostasis is a great advantage. Subsequent contractions of the uterine musculature also aid in the separation of the placenta.

Selective Action of the Suprarenal Cortex Secretion on Mesothelial Tissues.—Robert C. Moehlig (*American Journal of the Medical Sciences,* October, 1924) maintains that the suprarenal cortex secretion has a selective action on the mesothelial tissues. The normal development and continuous normal functioning of the sexual glands and skeletal muscles is dependent upon the normal functioning of the suprarenal cortex. Anterior cerebral defects include the pituitary gland, which in turn are accompanied by suprarenal cortex defects.

Mechanism of Acidosis.—Léon Blum and Maurice Delaville (*Presse médicale,* May 9, 1925) define acidosis as a condition resulting from rupture of the normal acid-base balance due to an increase of the acid valences. Hitherto this disturbance has been mainly considered the result of an increase of the acids, particularly the organic acids. But reduction of the bases may likewise bring about acidosis, and the authors recognize three forms of acidosis, *viz.,* those arising through hyperacidity, through hypoalkalosis, and through both of these conditions combined. These different forms occur clinically. The group of the acidoses through hyperacidity may be further divided into acidosis from excess of ketone bodies, or ketoacidosis, such as occurs in hydrocarbon starvation and diabetes; acidosis from excess of lactic acid, or lactoacidosis, which has been observed after violent and prolonged muscular exertion and probably plays a rôle in some diseases; acidosis from excess of hydrochloric acid, or chloroacidosis, met with in nephritis when elimination of chlorine is defective, and also produced by administration of large amounts of calcium chloride or ammonium chloride; acidosis due to proteins which seize upon bases, or proteinoacidosis, a condition which infiltration permits of demonstrating and which occurs in some cases of heart disease with edema. Acidosis through hypoalkalosis is by no means rare, and is a frequent cause of the acidosis in Bright's disease. The authors found it in two cases of osteomalacia; it may, perhaps, be concerned in the acidosis of rickets. Acidosis through combined hyperacidity and hypoalkalosis is met with in Bright's disease and more rarely in the extreme stages of diabetes.

GASTROENTEROLOGY

Observations on Causes of Gallstone Formation.—Peyton Rous, Philip D. McMaster, and Douglas R. Drury (*Journal of Experimental Medicine,* January, 1924), were able to produce gallstones in fourteen out of twenty-two dogs intubated for the collection of sterile bile. The bile out of which the stones formed was liver bile. Three general types of stones developed, one consisting almost wholly of calcium bilirrhinate, another of calcium carbonate, and a mixed type in which both compounds were present. The experiments demonstrate that gallstones can be formed in the absence of influences to which many authors have accorded a primary importance in their etiology, i. e., infection, stasis, and gall-

bladder activity. They are also not the result of bile loss, for similar stones may be recovered from the wall of glass tubes interpolated in ducts with intestinal connection undisturbed.

In another communication these authors discussed the factors concerned in the genesis of gallstones consisting of calcium carbonate. The evidence they have collected supports the view that the development of carbonate stones in human beings as well as in the dog may be a consequence, not of changes in the bile brought about by microorganisms, nor of the elaboration of an inflammatory exudate rich in calcium salts, but merely of inflammation such as leads to lessened motility of the duct system with the accumulation of organic debris. The fact that infection is almost the sole agent whereby such inflammation is set up and maintained in clinical instances has led too often to the conclusion that it serves as the essential agent in the process of calsification.

Cancer of the Esophagus.—Porter P. Vinson (*Medical Clinics of North America,* January, 1925) states that many physicians advise early, routine gastrostomy in these cases of malignancy. Others prefer radium and x ray treatment, and certain enthusiastic thoracic surgeons advocate resection. Since radium was found not to give relief, the author in his clinic adopted the policy of dilating malignant strictures with sounds just like benign strictures. The stricture is dilated up to 45 F. at the first treatment and the patient is told to return for later dilatations. This is only pallitative treatment. Gastrostomy is unsatisfactory.

However, there are certain types of malignant strictures that cannot be dilated, or in which dilatation fails to afford relief:

1. In cases of cancer of the introitus, with either unilateral or bilateral cord paralysis, metastasis to the cervical glands, and cough, no relief can be obtained by passing sounds. Neither is relief afforded by gastrostomy. Morphin alone gives the patient comfort.

2. If the lesion is essentially gastric, and obstruction is produced by shelving of the malignant growth at the cardia, sounds pass over this mass, and no real stretching is accomplished. Gastrostomy in such cases may result in metastasis to the abdominal wall at the site of the old incision and add permanently to the patient's discomfort.

3. Spontaneous performation into the bronchus or into the trachea makes dilatation inadvisable. In such cases the thread will wrap around the esophageal septum, and the sound cannot be guided, Gastrostomy is then possibly indicated, but should not be urged.

Results with radium have been absolutely disappointing. There are two outstanding dangers with x ray: the patient is incapacitated after treatment by nausea and vomiting, and there is a chance of producing pulmonary fibrosis with respiratory symptoms. X ray treatment is indicated only if the patient is in very good condition. Surgery is purely experimental and should not be advised.

Ninety per cent. of the cases can be diagnosed on the history alone: age beyond forty, progressive and constant dysphagia for a year or less, beginning with solid food, later with semi-solids, and finally with liquids, with or without pain, and without a history of swallowing a caustic. Roentgenography reveals, when positive, a typical picture: a moth-eaten, irregular appearing lesion. There may be a perfectly smooth obstruction; it also shows perforation into the bronchus. The passage of sounds is also helpful in diagnosis. Cancerous strictures can be dilated up to 45 F. without difficulty, which is not true of benign strictures. A specimen may be obtained through the esophagoscope for biopsy.

Appëndectomies at the Lankenau Hospital.—J. B. Deaver and J. A. H. Magoun (*Annals of Surgery,* June, 1924) review a considerable number of cases with the following conclusions: Acute appendicitis is, in the majority of instances, a disease of early adult life, although it may occur at any age. In neglected cases the patients will remain in the hospital from three to five weeks after operation. A purgative should never be given to patients with acute abdominal pain, until inflammation of the appendix is excluded. The mortality in this disease has decreased practically fifty per cent. during the last decade, and while the general increase in knowledge concerning it may partially account for this, it would seem as if the expectant treatment of spreading peritonitis, as described, is also of value. After the peritonitis has localized and a mass is present, the incision as described will be of value in the extraperitoneal approach to the ileum. In practically every case the appendix can be removed. Drainage varies with the situation of the abscess. Cigarette drains and pieces of gauze are commonly used, and occasionally as in pelvic abscess, a glass tube is used. The highest mortality follows subdiaphragmatic abcess or multiple abscesses. If the cecum or ileum is indurated or ulcerated at the primary operation, fecal fistula will occasionally occur. When the appendix, with the abscess lies under the terminal ileum, obstruction may follow. In conclusion, it should be emphasized that prompt diagnosis and appendectomy will do away with many of these serious postoperative complications.

Pancreatic Cysts.—Max Einhorn (*American Journal of the Medical Sciences,* March, 1925) says that the most important symptoms in cases of pancreatic cysts are fulness after meals, gastic distress and vomiting at times. The larger the cyst the more distress is present. The diagnosis of pancratic cyst is not difficult, provided the cyst has assumed considerable proportions and the clinician is aware of such a possibility. The marked features which help to recognize this disease are the following: There is a tumor usually in the left hypochondrium with a smooth even surface, frequently showing fluctuation. The principal protrusion appears to be in the left nipple line beneath the costal margin. The dulness produced by the mass on percussion does not extend to the spleen on the left side, nor to the liver on the right. Changes in the configuration of the tumor are of frequent occurrence, dependent upon the state of the stomach (whether the latter be filled or empty). There is a filling defect in the stomach due to pressure from the outside (recognizable by roentgen rays). Either a very rapid increase in the size of the tumor (within a month or two), or on the other hand a very slow protracted course (several years) is characteristic for a cyst.

In regard to treatment, there is only one course to pursue, and that is to operate as soon as the diagnosis is reasonably made; for without operation the condition usually leads to protracted illness, great suffering, and death. An operation, however, either removal of the cyst or aspiration and drainage after suturing the opened cyst to the abdominal wall—is ordinarily followed by a permanent cure; this occurred in the two cases described.

Carcinoma and Sarcoma of the Esophagus.—It was stated many years ago by Chevalier Jackson (*American Journal of the Medical Sciences,* May, 1925) that the mortality of malignant disease of the esophagus was, at that time, one hundred per cent. Notwithstanding the great advances made in the surgery of malignancy elsewhere in the body the ultimate prognosis of esophageal cancer remains the same today. There is every reason to believe, however, that the reason for this is that the surgeons have never had a chance to develop the technic of a curative operation because the diagnosis is never made early. The reason why the diagnosis is never made early is that the textbooks and journal articles give chiefly or exclusively diagnostic methods that are always negative early in the disease. When the time comes in which esophagascopy shall be resorted to promptly on the appearance of certain very vague symptoms there is ample justification for the belief that the surgeon will cure a good percentage of patients. Squamous celled endoesophageal carcinoma is not an aggressive type of malignancy. On the contrary, it is a mild, slow and, for a long time, purely local process.

Under palliative treatment, if the patient is never permitted to be short of an abundance of water and a full allowance of properly balanced food elements, in most cases the patients will survive at least two years from the onset of the disease, and some have survived as long as five years. One lived six years. Patients running the gauntlet of late inferential diagnosis, and leading a precarious existence of various degrees of food and water starvation, depressed and acidotic, on a diet of intermittent supplies of raw eggs and meat broths, may not survive more than a year from the probable time of the onset of the disease.

The bougie as a diagnostic means is not only dangerous, but it is inconclusive because inferential; and it is always hopelessly late. A cancer must be well advanced before it will stop a bougie. Even fatal cancer of the esophagus may not be obstructive. The bougie as a therapeutic measure hastens death either by perforation or by increasing metastases. As stated by Da Costa, "no surgeon would stretch a cancer." As stated by Shallow, "no surgeon would

forcibly dilate malignant stricture of the esophagus any more than he would forcibly dilate cancer of the rectum."

There are only two means by which an early diagnosis of esophageal malignancy can be made, namely: Röntgen ray examination, and esophagoscopy. All other means are late, inconclusive, and some of them dangerous. By esophagoscopy endoesophageal cancer can be diagnosticated not only early, but with the absolute certainty essential to getting the consent of a comparatively well man to an operation he may not survive. Endoesophageal cancer can be diagnosticated just as early, just as quickly and just as certainly as cancer of the cervix if an opportunity for esophagoscopy is afforded early.

RESPIRATORY TRACT

Blood Plate Counts in Pulmonary Tuberculosis.—R. G. Bannerman (*Lancet*, September 20, 1924) found that the blood plates are generally present in excessive numbers in active pulmonary tuberculosis, and that, broadly speaking, the more serious the clincal condition the greater is the degree of thrombocytosis. In some cases, where repeated counts have been made at intervals, a change in the number of plates has occurred. When the change is in the direction of the normal, it has coincided with an improvement in the clinical condition, where as a movement in the opposite direction, or the persistence of a high plate count, has been associated with progression of the disease. On the other hand, the maintenance of a normal plate count points to stability. More prolonged observation is required to determine the more precise relations between thrombocytosis and the stage of the disease, but it is already apparent that there is no necessary correspondence between the number of plates and such features as pyrexia, the anatomical extent of the disease, or the presence of tubercle bacilli in the sputum. It appears rather that there exists an inverse relation between thrombocytosis and the subject's resistance to the disease; it is suggested that the plate count may afford a means of measuring that somewhat indefinite entity, which is the basis of prognosis.

Autohemotherapy in Essential Asthma.—L Rimbaud (*Bulletin de la Société des sciences médicales de Montpellier*, November, 1923), reports the case of a woman aged thirty-three who had been suffering from asthma for two and a half years, the disorder having begun in the seventh month of pregnancy. For the last year the attacks had been recurring generally once a week, and regularly at the menstrual periods. A variety of organic products and vaccines, together with iodides, lobelia, digitalis and cacodylates had been tried without appreciable result. Clinical evidences were against the existence of tuberculosis. The patient was sensitive to new mown hay. Ten mils of blood were withdrawn from a vein at the bend of the elbow and reinjected in the gluteal region. Nine more such injections were given at weekly intervals. The first two injections were followed on the next day by some lassitude and a slight attack of dyspnea. In the succeeding four months, however, up to the time of writing, she had not had a single asthmatic attack.

Pleurisy of the Hilum Region.—H. Swanberg (*Surgery, Gynecology and Obstetrics*, April, 1924) gives a report of a case and the following conclusions. Pleurisy of the hilum region can be successfully diagnosed only by a combination of a careful history with a roentgenological study. Without a careful history the increased hilum shadow might be interpreted as a mediastinal tumor, glandular masses, or limited pulmonary lesions. Because of the fetid odor such cases may simulate pulmonary gangrene. However, in pulmonary gangrene, the fetid odor precedes the expectoration, stethoscopic signs are more important, and the general condition is more serious.

Nontuberculous Pulmonary Abscess.—W. Whittemore (*Surgery, Gynecology and Obstetrics*, April, 1924) says that it is important for the surgeon performing operations on the upper respiratory tract under general anesthesia to bear in mind the danger of lung infection and arrange his technique so as to avoid this complication. From ten to thirty per cent. of the cases may be expected to be cured by expectant treatment. Artificial pneumothorax may cure a very small number of cases. It should be used only in those cases in which the lung and costal pleura are not adherent. It is an excellent means of determining whether or not adhesions are present. Bronchoscopy may cure a very limited number of cases if treatment is established early. Surgery offers an excellent chance for cure in those cases in which other methods of treatment have failed or are unsuitable.

Value of Physical Signs in the Early Detection of Pulmonary Metastases.—Lloyd F. Craver (*American Journal of the Medical Sciences*, June, 1924) says that it is essential to search carefully for the presence of metastases before planning the treatment of malignant neoplasms and describes the physical signs of early as well as late stages of metastasis to lungs and pleura in two typical types of malignant neoplasms in which such secondary growth frequently occur, mammary carcinoma serving as an example of carcinoma, and osteogenic sarcoma as one of sarcoma. The earliest physical sign of metastasis to pleura or lung from breast carcinoma is a patchy limitation of breath sounds, particularly during inspiration, which may or may not be accompanied by crackling rales or pleural friction rubs. It may be detected in some instances before the röntgenologist is able to demonstrate any shadow distinctive of metastasis. The later signs correspond to those described in textbooks. The earliest demonstrable physical signs of chest metastasis of osteogenic sarcoma may not appear until some time after the röntgen ray has succeeded in showing the small, round, well circumscribed nodules.

Artificial Pneumothorax.—L. S. T. Burrell (*Lancet*, July 26, 1924) maintains that artificial pneumothorax should be regarded not as a cure for tuberculosis of the lung, but as a safe method of resting the diseased part, and it should be used in conjunction with other methods of treatment. The success of the treatment is largely dependent on really keeping the lung at rest, taking each case individually and arranging the dosage and intervals between the refills according to the peculiarities of the individual patient.

NEUROPSYCHIATRY

Staphylococcus and Streptococcus Meningitis.—W. E. Dandy (*Surgery, Gynecology and Obstetrics*, December, 1924) advocates early continuous drainage of the cisterna magna for the treatment of meningitis in which the infecting organism is staphylococcus and streptococcus. This method is not urged in other forms of meningitis because it is felt, though not proven, that the character of the inflammatory exudate would probably make drainage impossible.

Meningocerebral Adhesions.—W. G. Penfield (*Surgery, Gynecology and Obstetrics, December*, 1924) has found, from a histological study of the result of cerebral incision and cranioplasty, that after a simple brain wound active phagocytosis continues over a long period and with it progressive disappearance of brain structure. Neurones adjacent to such an area of rarefaction may show chromatolysis as late as seven months after operation. Between normal brain structure and such rarefaction is found a brush work of neuroglia cells and sometimes a limiting layer of neuroglia fibrils. In the cavity is found a loose connective tissue network. Deep adhesions are composed of connective tissue threads attached to dura, or its substitute, and to the glia brushwork at the bottom of the brain wound. Superficial adhesions result from slight injury and extend some little distance over the surface of the brain from the point injured. These adhesions are composed of an interlacement of connective tissue fibrils from the dura, with the fibrils of a superficial gliosis. The thickness of the new or adventitious dura, formed after removed of the old, varies according to the available blood supply. Movement and foreign bodies are also factors to be considered. The dura is thick after a decompression operation and thin beneath a bone flap.

Placement of the least irritating foreign bodies, as celloidin, on the surface of the brain causes a very thick, hard connective tissue envelope to form all about it. The results are the same even when there is no wound of brain and when the foreign body lies beneath a relatively nonvascular bone flap. The layers of this envelope form a bursalike cavity preventing direct adhesion to the scalp or skull. Adhesion between brain wound and lower layer of the envelope forms, of course, as well as adhesion between upper laver and skull or scalp. Transplantation of various tissues to the surface of the brain is followed by rapid growth of a layer of fibroblasts above and beneath the transplant. Such procedures are useless if their purpose is to prevent adhesions, for fibroblasts grow wherever the wound. Thus the transplant is incorporated in the adhesion conditions are suitable as do organisms in a contaminated of brain to its covering.

GYNECOLOGY AND OBSTETRICS

Vagotonia in Pregnancy.—By means of injections of epinephrine, L. C. Louros (*Zentralblatt für Gynäkologie,* August 30, 1924) was enabled to produce a continually increasing hyperirritability of the vagus nerve in preganancy. The hypofunction of the sympathetic nerve produces a lowering of the blood pressure. The paradoxical increase of the pressure is produced by local changes in the blood vessels by substances manufactured during pregnancy. The author maintains that the injections should be given subcutaneously and that the resulting blood pressure curve may be regarded as an index of the vagotonia of pregnancy.

Is the Kielland Forceps an Axis Traction Forceps?—Hans Heidler (*Zentralblatt für Gynäkologie,* August 16, 1924) calls attention to the fact that the great point of differentiation of the Kielland from other types of forceps is the fact that the former has no pelvic curve and therefore it can be applied biparietally in the pelvic inlet. Aside from this it fulfills all the demands made on an axis traction forceps. The evidence for this is seen in röntgenograms, which show that the lock of the forceps pushes the coccyx backward and consequently the direction of the traction is more in a backward direction than in the usual type of forceps.

Treatment of Disturbances of the Third Stage of Labor.—If the placenta does not descend within half an hour, Hans Heidler (*Wiener klinische Wochenschrift,* August 14, 1924) injects three hundred c.c. of sterile physiological sodium chloride solution into the umbilical vein. If this procedure does not produce the desired result, the injection may be repeated twice, if necessary at intervals of half an hour. If this maneuvre is unsuccessful, pituitary extract or ergot may be injected. Manual removal of the placenta is the last resort. If done early, under aseptic precautions and in an uninfected woman, this interference is not as dangerous as is generally assumed. If this operation is done during the febrile stage in an infected woman, or if the uterus is examined within a few days after the delivery, the result is usually fatal.

Pyelitis of Pregnancy.—E. Klaften (*Zentralblatt für Gynäkologie,* August 9, 1924) mentions the following symptoms of the pyelitis of pregnancy: High fever and pains in the region of the kidney with muscular rigidity, so that it may be confused with appendicitis when it occurs on the right side. Of thirty-three patients, sixteen showed nothing abnormal clinically or bacteriologically and the rest, subjectively normal at times, showed leukocytes and colon bacilli in the urine. The colon bacilli are also found in the lower two thirds of the vagina, from which they may be made to disappear after injections of lactic acid. These injections constitute a part of the treatment, which consists mainly in the use of urotropin. A forty per cent. solution of urotropin is injected intravenously in amounts of five to ten c.c., which dose may be repeated after twelve hours and again twice on the second day, provided the bladder is not irritated. The patient is given nothing or almost nothing to drink, kept in bed and should be made to lie prone or on the side of the healthy kidney. A milk diet is ordered and laxatives are indicated. About five days after the retrogression of the acute symptoms one gram of urotropin is given by mouth three times daily, possibly reenforced by ten drops of diluted hydrochloric acid. In obstinate cases the pelvis of the kidney may be irrigated. The interruption of pregnancy is indicated only in patients with one kidney.

Sedimentation of Erythrocytes Test in Obstetrics and Gynecology.—Béla Falta (*Zentralblatt für Gynäkologie,* July 5, 1924) draws the following conclusions: The increased rapidity of sedimentation of the erythrocytes is a constant sign of pregnancy after the fourth month. The rapidity of the reaction increases with the progress of the pregnancy, reaching its highest stage during the delivery. Owing to individual variations the terms of pregnancy cannot be determined. During the first eight to ten days of the puerperium, the values were found to be the same as during labor; subsequently it is diminished, to return to normal after the course of three weeks. The rapidity of the sedimentation is strikingly increased in beginning or threatened abortion, just as in hemorrhages of postpartum endometritides. In adnexal inflammations the rapidity of sedimentation is markedly increased, but in cases showing the presence of virulent germs it is normal. This test can be used in the differential diagnosis between ectopic pregnancy and adnexal tumor only with the most accurate consideration of all the other factors. In benign tumors the rapidity of this test is normal in contrast to the malignant tumors, in which it is markedly increased. In many cases of carcinoma this reaction appears to run parallel with the extension of the disease, but not regularly so. It indicates recurrences very early.

Limits of Control by Sense of Feeling of Intrauterine Use of Instruments.—Hugo Sellheim (*Zentralblatt für Gynäkologie,* July 5, 1924) says that the sensations imparted by the uterine sound, placenta forceps and curette may be misleading. The utmost care is necessary and the curettage should be repeated in clinically suspicious (carcinoma)' cases of hemorrhage at the climacterium. Ergotin and pituitrin should be given in a preliminary way before treating abortions so that the uterus may contract with the progressive emptying of the uterus. The placenta forceps has no advantages over the finger as it does not reach beyond the nondangerous area reached by the finger.

Placenta Accreta.—J. O. Polak and G. W. Phelan (*Surgery, Gynecology and Obstetrics,* February, 1924) offer the following conclusions:

1. In our series the incidence of placenta accreta is about one in six thousand cases.
2. There is considerable confusion in the minds of the profession between simple adhesion of the placenta and true accreta.
3. Accreta is a definite pathological entity.
4. Manual removal is impossible and can only result in hemorrhage, sepsis, or perforation.
5. Every delayed placenta with no hemorrhage should be viewed with suspicion; and no attempts at Credé's method should be made if the clinical signs of separation are not present.
6. In the presence of an attached placenta without bleeding, aseptic exploration under anesthesia should be made to determine the subsequent procedure.
7. Finally, if no line of cleavage can be demonstrated, hysterectomy should be done.

Prolonged Rest in the Horizontal Position a Fertile Cause of Puerperal Sepsis.—Henry Corby (*British Medical Journal,* September 27, 1924) is impressed by the fact that puerperal sepsis is almost unknown among women in the slums in spite of their contempt for the belief that ten days to two weeks of rest should be taken after a confinement. These women often do their regular household duties as early as the third day after labor.

Nature's methods of defending the organism against bacterial infection are the following: In the first place there is the vaginal bacillus, which is an efficient sentinel against pathogenic bacteria entering the vagina. During labor the rush of amniotic fluid tends to flush out any bacteria that may be present. The downward passage of the child's body during delivery tends to brush them out firmly. The expulsion of the secundines produces a similar result, and the afterbleeding helps to complete the work.

The arguments advanced against early rising of the patient include the possibility of pulmonary embolism. But this is rare and, besides, it depends upon the suddenness of the change in position. The second argument is the occurrence of prolapse of the uterus from relaxation of the uterine ligaments, and this is also rare among these women. Besides, during the puerperium the uterus has no need for the suspensory ligaments and its bulk gives it support from the surrounding structures. The bugaboo of uterine displacements and resulting abortion is also put out of the way by the actual rarity of this occurrence among the women living under poor conditions.

Judging by the energetic efforts of Nature to get rid of noxious bacteria, the lochia must also wash out a large number of the pathogenic germs. Retained pieces of the secundines are more readily expelled in the upright than in the recumbent position. Furthermore, the lochia retained in the uterus interferes with adequate involution of the uterus in the recumbent position, thereby favoring sepsis. The author instructs his patients to sit up at stated intervals in bed and favors early rising after the confinement.

NEW YORK, WEDNESDAY, SEPTEMBER 16, 1925

Medicolegal Notes.

EMPLOYER'S LIABILITY FOR MEDICAL TREATMENT

The New York Appellate Division holds, Balderson v. Wallace and Co., 208 N. Y. Supp. 543, that under section 13 of the Workmen's Compensation Law, prior to its amendment in 1922, an employer was not liable for medical treatment and nursing furnished more than sixty days after the injury where this was not required by the State Industrial Commission and the employer given the opportunity to furnish it by suitable persons of its own selection. The amendment of 1922 strikes out the provision as to the requirement of such treatment by the commission, and makes liability therefor by the employer depend on "the nature of the injury or the process of recovery," without limitation as to time. But this amendment is not retroactive.

SEPTICAEMIA FROM TOUCHING DEAD BODY NOT COMPENSABLE

The New York Appellate Division holds, Connelly v. Hunt Furniture Co., 207 N. Y. Supp. 695, that death from septicaemia resulting from touching a gangrenous body which the deceased employee was preparing for burial was not compensable under the Workmen's Compensation Act. "The contact made was intended to be made, and did not involve an occurrence or happening, sudden or unexpected. Moreover, the contact was not in itself an injury. There was no traumatism and no immediate physical hurt."

PNEUMONIA CONTRACTED WHILE WORKING IN ICEBOX NOT AN ACCIDENT

The New York Appellate Division holds, D'Oleveri v. Austin, Nichols & Co., 211 App. Div. 295, 207 N. Y. Supp. 699, that pneumonia, contracted by a food packer while working in an icebox in a storage warehouse was not compensable as an accident. "The hazard, if it might be so called, was a continuous one, known fully to the claimant, and his act a voluntary one; therefore not accidental, and referable to no moment of time which was definite."

MISSISSIPPI PRIVILEGED COMMUNICATIONS STATUTE

The Mississippi Supreme Court holds, Dabbs v. Richardson, 102 So. 769, that, under the state statute, a physician is not a competent witness to testify as to facts and information received by him in his capacity as a physician. He is a competent witness to testify, in proceedings to probate a will, concerning the mental condition of the testator, though he was his physician, if his information is derived from social or business relations and not by professional relations. But where his knowledge is derived partly from his relation as a physician and partly from social and business relations, it is held that the trial judge may determine his competency in view of all the evidence, and if it appears that his information as a physician influenced his judgment, the judge may exclude his evidence from the jury.

OSTEOPATH CANNOT PRACTISE OPTOMETRY IN KANSAS WITHOUT REGISTERING

The Kansas Supreme Court holds, three judges dissenting, State v. Eustace, 233 Pac. 109, that a registered osteopath is not entitled to practise optometry in Kansas without registering as an optometrist in the manner required by law. The court says that osteopathy when practised by a physician or surgeon as defined in section 65-1005 Kansas Revised Statutes "may be and probably is a part of the art or science of healing, but the practice of osteopathy, while it may be a part of the art of healing, is not comprehended within the term 'practising medicine,' nor within the term 'surgical operation' as used in section 65-1005 of the Revised Statutes. Section 65-1508 of the Revised Statutes, providing that nothing in the optometry act shall be construed as preventing regular registered physicians and surgeons from practising optometry, does not include those who are registered to practice osteopathy."

ESTABLISHMENT OF CORPUS DELICTI IN MURDER CASES

The California courts hold, People v. Clark, 233 Pac. 980, that, in a murder case, the general rule requiring either the production of the body of the person supposed to have been murdered or some circumstance from which death would necessarily follow cannot be applied in all cases. "If the circumstances surrounding the disappearance of the alleged victim be such as to convince the mind to a moral certainty as to his death, the demands of the law will be satisfied. Nor is it necessary in establishing the corpus delicti that the means by or through which such death resulted be established beyond a reasonable doubt." But the California cases hold that the corpus delicti must be established without the aid of any admission by a defendant.

JUDICIAL NOTICE THAT MORPHINE SULPHATE IS NARCOTIC

The Oklahoma Criminal Court, Barr v. State, 231 Pac. 322, takes judicial notice of the fact that morphine sulphate is a narcotic drug, as defined by section 8886, Okla. Comp. Stat., 1921, and that the dose varies from one twelfth to one half of a grain.

QUALIFICATION AS MEDICAL EXPERT WITNESS

In a murder prosecution, where it was alleged the deceased was killed by arsenical poisoning, it was contended that a medical witness for the prosecution who gave an opinion as to the cause of death was not shown to be an expert, because "there was no qualification with regard to experience in connection with poisoning cases or arsenical poisoning prior to the admission of this evidence." It was held, People v. Potigian, (Cal. App.), 231 Pac. 593, that "a physician may testify as an expert, touching cause of death, basing his opinion upon special knowledge acquired from professional study, even though he may have had no practical experience in cases of the kind concerning which he testified."

FOUNDATION FOR DYING DECLARATIONS

The New Mexico Supreme Court holds, State v. Stewart, 231 Pac. 692, that a dying declaration is admissible in evidence only when it is shown that the declarant was conscious of the approach of death at the time it was made; and where the only evidence of such consciousness on the part of the declarant is the character of the wound and the state of his illness, such a declaration cannot be admitted, where all the surrounding facts and circumstances indicate that no such consciousness existed.

REFUSAL TO SUBMIT TO MEDICAL AND SURGICAL TREATMENT

The Oklahoma Supreme Court, Chicago Bridge & Iron Works v. Sabin, 237 Pac. 851, holds that where an employee is injured and claims compensation under the Workmen's Compensation Act, and receives it up to and including the date when he should have been cured had he submitted to medical and surgical treatment in no manner endangering life in the slightest degree, or causing pain, he cannot recover compensation for increase of disability due to his failure to accept such treatment and use ordinary care to avoid aggravating the injury.

Diagnostic Value of X Ray Examination of the Gallbladder After the Intravenous Injection of Tetraiodophenolphthalein*

WALTER C. BARKER, M.D.
Philadelphia

In the past the röntgenographic study of the gallbladder has been limited to finding gallstones in about fifty per cent. of the patients who had them, and when the hollow viscera were filled with a contrast fluid, in noting the effects of adhesions resulting from pericholecystitis. At times that which appeared to be the shadow of the gallbladder was interpreted as a hyperplasia of its wall. Only when the x ray findings were positive for gallstones, have these observations been of value to the clinician.

In reference to the gallbladder, the problem to be solved may be stated under three headings. First, is the gallbladder the primary seat of infection or secondary? Second, are gallstones present or absent? Third, does the gallbladder function properly?

In solving the first portion of the problem, the differential diagnosis must be studied. A number of cases in the series forming the basis for this paper had a complete abdominal x ray examination and chronic appendicitis was found in six of the cases, duodenal ulcers in three, and in all of these patients the gallbladder behaved normally. When indefinite symptoms are present, the urological tract should be examined to eliminate the possibility of renal calculi, growth and obstruction of the right ureter. The ileocecal region should be observed, especially for alterations in motility, as the ileocecal reflex plays an important part in referring symptoms to the pyloric region of the gastrointestinal tract. The duodenal and gastric regions should also be carefully studied.

If by the direct examination gallstones are found, this solves the second portion of the problem.

After excluding pathological conditions outside of the gallbladder and gallstones by the direct method of x ray examination, there remains a large group of cases in which the character of the functioning of the gallbladder must be determined.

Considering the frequency of gallbladder disease, it seems remarkable that until recently so little research work has been done on the study of the physiology of this organ. The old slogan that gallstones represent the terminal stage of infection and therefore all patients having gallbladder disease require surgical drainage or cholecystectomy, has been exploded, because in many patients in whom the primary results were good, after a limited period of time the old symptoms recurred. To determine the cause of the postoperative symptoms, intensive study has been made which has opened the field for a better understanding of gallbladder function. The unfavorable results of operations are found to be due in part to infections of the biliary ducts, or because the sphincter of Oddi would not close, and thus the normal physiological balance and rhythm which exist between the mechanism of the gastric pyloric sphincter, the sphincter of Oddi, and the contraction of the gallbladder, are lost, so that the liver keeps up a continuous flow of bile, and serious digestive disturbances occur. This does not happen in every case for in those patients in whom the sphincter of Oddi continues to function after the removal of the gallbladder, the biliary and common ducts may distend, and as they are lined with columnar epithelium similar to that which form the gallbladder mucosa, the function of concentration of bile salts is here continued.

The function of the gallbladder may be better understood by briefly stating some of the observations made by Mann of the Mayo Clinic in Rochester, Minn., in the study of the mechanism of the function of the gallbladder by animal experimentation.

Mann introduced a tube into the gallbladder of an animal and another one into a biliary duct. By attaching these tubes to a mercury column he was able to measure variation in pressure. During gastric digestion, the pressure from the gallbladder was lowest, and after gastric digestion was completed the pressure gradually increased. From this observation the deduction is made that the gallbladder empties during gastric digestion and fills during the fasting stage. When concentrated bile salts from one animal were introduced into the duodenum of the animal with a tube in a biliary duct, there was a marked increase in the flow of bile from the liver. Therefore it seems that concentrated bile salts stimulate biliary secretion. Since gallbladder bile has a greater concentration of the bile salts than the hepatic bile, Mann formulated the hypothesis that a chemical reaction takes place when concentrated bile from the gall-

bladder comes into contact with duodenal secretions, forming a hormone similar to the hormone known as duodenal secretion, which stimulated pancreatic secretion, or to the gastric secretion which stimulates the flow of gastric secretion. This hormone is taken up through the duodenal mucosa into the blood stream and acts directly upon the secreting cells of the liver.

Another important observation was made by Mann which was that when rose benzol, a red dye, was injected intravenously into the animal with the tube in the gallbladder, the bile from the gallbladder was mixed with a large quantity of this dye, and when the cystic duct was ligated a small quantity of the dye was recovered from the gallbladder. The deduction here is that the gallbladder has the power of taking substances from the circulation and secreting them into its cavity.

A Japanese observer, Matsuo, opened the abdomen of an animal and injected azarubin S into the gallbladder. He then by the method of Lyon relaxed the sphincter of Oddi and saw the gallbladder rapidly diminish in size, and was also able to reclaim bile mixed with dye through the duodenal tube. This observation seems to establish the statement that there is a reflex action between the sphincter of Oddi and the emptying of the gallbladder.

From the observations of these men and others it appears that the gallbladder has a definite function which is to establish the activity of the biliary secretion during gastric and duodenal digestion, and that the mechanism of this function is regulated by a reflex stimulation which empties the gallbladder when the sphincter of Oddi is relaxed.

In the light of these facts, before starting x ray examination for a study of the gallbladder condition,

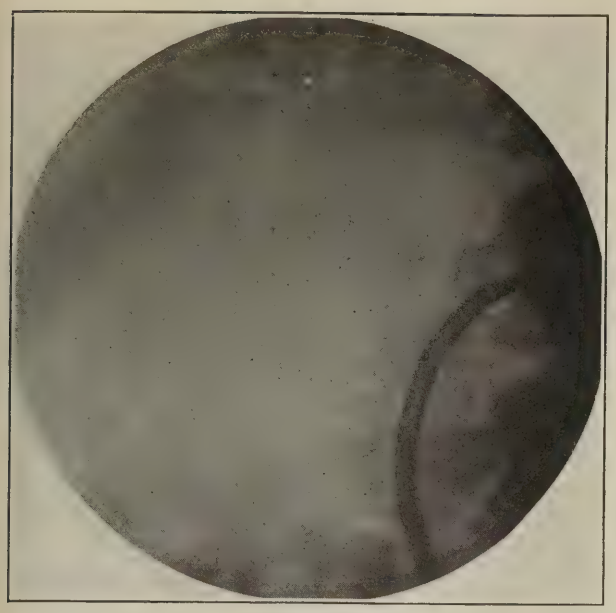

FIG. 5.—Plate made fifteen minutes after Fig. 4.

FIG. 6.—Plate made after draining gallbladder for forty-five minutes.

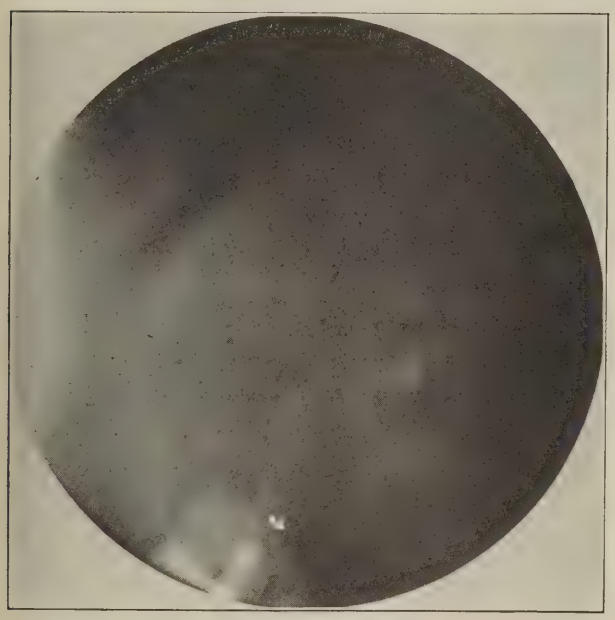

FIG. 7.—Common duct obstruction. Gallbladder injected with tetrabromphenolphthalein; did not appear in gallbladder.

certain preparations for the patient are necessary. No food must be taken into the stomach for a period of six to twelve hours. This is to insure the closing of the sphincter of Oddi and the storing of bile in the gallbladder. The usual cleansing of the colon of fecal matter and gas is essential for clear shadows.

Graham and Cole, of St. Louis, introduced the use of tetrabromphenolphthalein for visualization of the gallbladder. The phenoltetrachlorphthalein was first used by Orndorff and Black as a chemical test of liver function, but the specific gravity of this salt is not high enough to cast a shadow to x rays in contrast to that of the soft structures. Tetrabromphenolphthalein when injected into the vein in strengths of 0.1 gm. per kilogram of body weight, is eliminated into the bile by the liver and appears in the gallbladder in sufficient density to cast a definite shadow to x ray projection.

Whitaker and Milliken substituted for the bromine salt, tetraiodophenolphthalein. Because of its greater atomic weight this may be used in smaller quantities and produces a shadow as dense to the x rays as the bromine salt. It has about the same toxicity as the bromine salt but as it is used in smaller doses there is less reaction following its injection.

All of these salts are irritating to the veins and great care and caution must be exercised in their use. Of course, the usual aseptic methods employed in surgical procedures must be followed. To prevent necrosis, none of the fluid must be permitted to enter the tissues around the vein. Unless the vein is carefully washed after the introduction of the dye thrombosis is likely to result. However, if the intravenous injection is skillfully given, these local disturbances will be greatly minimized. There are many toxic symptoms which sometimes occur. Very

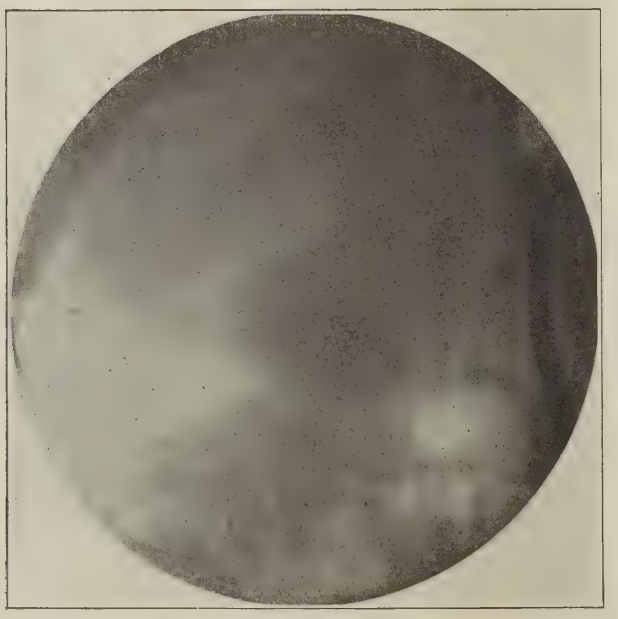

Fig 11

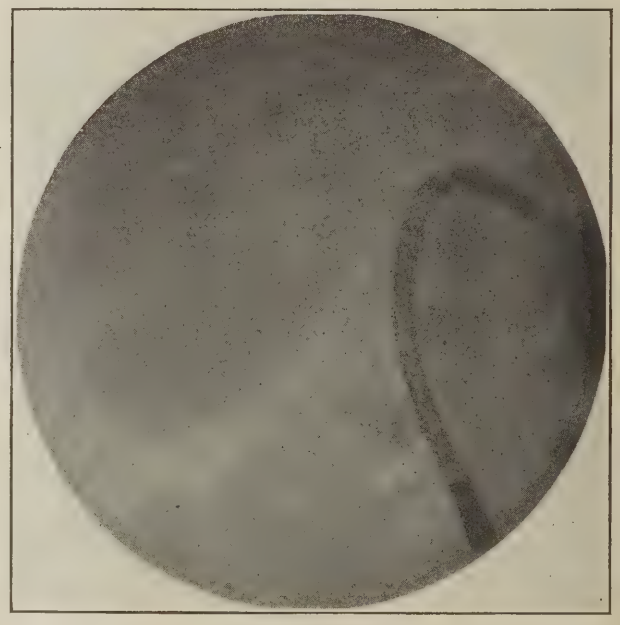

Fig. 12

Figs. 9, 10, 11, and 12.—Showing a gallbladder which failed to empty to stimulation of the sphincter of Oddi with magnesium sulphate, peptones, or olive oil. The film made thirty hours after the injection, and after three full meals showed as much of the dye stained bile in the gallbladder as was present at the eight hour examination. A diagnosis of spasm of the cystic duct was made. Subsequently this patient had an attack of appendicitis, and an appendectomy was performed. At the time of the operation the gallbladder was pronounced normal, and since the operation the patient has been free from symptoms referred to the gallbladder.

severe reactions have been reported, but so far all the patients have recovered. Many have no reaction whatever, but when we consider that patients with diseased gallbladders have very poor function of this organ and hence delayed elimination of the salt, reactions must be expected. Usually these are limited to pain in the back, headache, and nausea, but sometimes vomiting and stimulation to micturition and defecation will occur. A few cases of collapse have been reported. This seems to be due to the marked lowering of the blood pressure.

Menees and Robinson first advocated the oral administration of sodium tetrabromphenolphthalein asserting for this method the convenience of administration and diminution in amount of discomfort.

The method of raying is important. Control films are made before the dye is injected. If by the end of one hour the patient has sufficiently recovered from the reaction films are made, and when necessary the examination is continued hourly, for a period of eight or ten hours, depending upon conditions found. Before concluding that the dye has not appeared in the gallbladder, it is necessary to divide the right side of the abdomen into four or six areas and make an exposure of each of these areas. Because the secondary radiation may obscure a gallbladder shadow, when it contains but a small quantity of the dye, the results shown by one large film covering this entire area are not conclusive.

Anatomically, the gallbladder may be divided into

the fundus which is surrounded by peritoneum, the body and the neck. The last two are fixed to the under surface of the liver by folds of the peritoneum. If the body and neck are completely surrounded by the peritoneum, this will act as a mesentery and permit the gallbladder to find a lower position in the abdomen. The neck of the gallbladder is narrow and sometimes contains a dilated portion known as the ampoule of the gallbladder. The cystic duct is S shaped, and the mucosa and submucosa form folds which are diagonally situated forming a sort of screw effect which delays the filling and emptying of the gallbladder.

Owing to the fact that the examination is started six to twelve hours after the last meal, the gallbladder should be filled with bile. In many cases within a half hour after the injection of the dye the outline of the shadow of the gallbladder appears. It would seem, therefore, that some of the dye is taken up from the blood stream in the cystic circulation and secreted into the bile filled gallbladder cavity. In many cases the gallbladder appears at its greatest size at the end of four hours. Eight or ten hours after the injection the shadow of the gallbladder is smaller and denser. It would seem, therefore, that not only more dye enters the gallbladder, but that the fluid is absorbed so that the concentration of bile salts is being accomplished. This change in the size of the shadow of the gallbladder is an observation which should be made to determine the elasticity of its walls, because concentration of the bile salts cannot take place if there is a marked hyperplasia of the gallbladder wall. This increase in size may not appear before eight or ten hours after injection. A large sized gallbladder observed early in the course of the examination does not mean that the gallbladder is dilated. In order to establish this diagnosis it must remain dilated over a considerable period of time. A marked diminution in the size of the gallbladder throughout the examination, should be interpreted as a hyperplasia of its wall, but it may also be due to an open sphincter of Oddi which prevents the storing of much bile in the gallbladder.

After a full meal and when gastric digestion is well established, there should be a marked decrease in the size of the gallbladder. Twenty-four hours after the injection and after two meals, usually a trace of the salt remains in the gallbladder.

If the injection is properly given and the films are of good quality and made in a half second exposure or less, and no shadow of the gallbladder appears at any time during the twenty-four hour examination, a diagnosis of cystic duct obstruction may be made. This obstruction may be due to stricture, stones in the duct, or such a complete filling of the bladder with stones that the dye cannot enter.

In one case of the series no dye or bile left the gallbladder for thirty hours. The sphincter of Oddi was relaxed by Lyon's method but the gallbladder did not empty. There was no reduction in the amount of contents after meals. This condition may have been due to spasm of the cystic duct. To establish the correctness of this interpretation the observation will require repetition and further study.

To summarize, even though the gallbladder seems to be the seat of disease it is important to exclude pathology in other portions of the abdomen. This examination does not therefore in any way take the place of the usual x ray study of the abdomen by the use of contrast meal, and the direct method of projecting the shadows of the solid organs.

The advantages of visualizing the gallbladder by first filling its cavity with a contrast fluid, consists in the ability to determine whether shadows suspected of being due to gallstones are inside or outside the lumen, and to detect also the presence of stones within the body of the gallbladder which stones do not obstruct the cystic duct, or completely fill the cavity of the gallbladder so that bile can not enter.

If the sphincter of Oddi is contracted and the shadow of the gallbladder does not appear before ten hours, a diagnosis of dysfunction of the liver may be made. If the cystic duct is patent, it is unlikely liver dysfunction will be so diminished that the dye will not appear at all in the gallbladder. Therefore this method of examination will give positive evidence of obstruction of the cystic duct.

When mechanical defects are found, such as obstruction of the cystic duct or gallstones are present, the choice of therapy must be surgical. On the other hand, if the gallbladder is found to function and its wall is elastic and it drains completely within forty-eight hours after the intravenous injection of the dye and no gallstones are present, the patient may be treated by duodenal drainage.

The author's references will appear in his reprints.

The Röntgen Diagnosis of Duodenal Ulcer*

VICTOR KNAPP, M.D.
New York

It might be well to preface our remarks with a short history of duodenal ulcer. It was first recognized and described by John Abercrombie of Edinburgh in 1831. From then until 1910 it received but scant attention, when Moynihan published his excellent and comprehensive clinical discussion of the subject. It remained for the American school to make the first advances in the röntgenology of the disease; and credit must be given to L. G. Cole for his pioneer efforts in the study of both the normal and pathological röntgen interpretation of duodenal shadows. For the more recent advances we are indebted to Akerlund, who did such notable work in the clinic of Forsel; he made a very searching inquiry into the röntgen manifestations of normal and diseased duodenums. And we owe our present thorough understanding of the röntgenology of ulcer to him.

This method of diagnosis has achieved such per-

fection that we find authorities like Carman of the Mayo Clinic reporting ninety five per cent. correct positive diagnosis as proved by operation; and Holland of this city reports a slightly higher percentage. This approach to almost absolute certainty in positive diagnosis is something that cannot be asserted for many methods in use in the practice of medicine. However it is not to be inferred from these statistics that a similar exactness attends the negative diagnosis of the disease; for where such negative findings are reported, we have no way, in many instances, of proving the correctness of our assertion. Very often the diagnosis offers difficulties. But all things considered, the röntgen ray affords us a means of invaluable aid in the study of duodenal ulcer.

The normal duodenum (Fig. 1) is more or less triangular in shape, its borders are regular, the base is directed towards the pylorus, the pyloric sphincter is situated centrally, and there are no Kerkring folds present. This portion of the duodenum is freely movable. In this discussion in speaking of the duodenum, the first portion is meant; also it is called the cap or bulb. So that we shall use these terms interchangeably. Of course, the normal duodenum varies greatly in size and shape according to the habitus of the patient, as do all the organs of the body. It is important to note the difference in contour of the normal cap with various degrees of filling, and it is necessary that some such serial study of the cap as illustrated be made in order to determine its status.

This is a point that must be stressed and we shall call attention to it again in the consideration of the pathological duodenum. The second and third portions of the duodenum show the characteristic Kerkring folds. These segments are rarely the seat of disease, *per se,* but may be involved by contiguity from pathology in surrounding viscera. These portions are firmly held down by peritoneum to neighboring organs and to the posterior abdominal wall.

Ulcer of the duodenum usually occurs in the cap, and then is visualized on the lesser curvature of the cap, although anatomically it is usually situated on the posterior wall near the lesser curvature. The lesser curvature of the duodenum is that border which follows the lesser curvature of the stomach, and the greater curvature of the duodenum is that border which follows the greater curvature of the stomach. Ulcer of the duodenum will alter the regular contour of the cap in some way.

The niche is the characteristic röntgen sign of ulceration in the gastrointestinal tract (Fig. 2). As seen in the illustration, the niche must be differentiated from the visualization of a fold of the descending duodenum, when this organ takes a position directly behind the cap. This is accomplished by radiographing the patient in the oblique position; or else during the fluoroscopic examination, when the patient is placed in various positions, and the filling and emptying of the entire course of the duodenum may be observed. A filled cap may obscure an otherwise demonstrable niche (Fig. 3), and only when the cap is partially emptied is the niche apparent. This brings out the point made above of the need for serial röntgenography of the cap, and a study of its

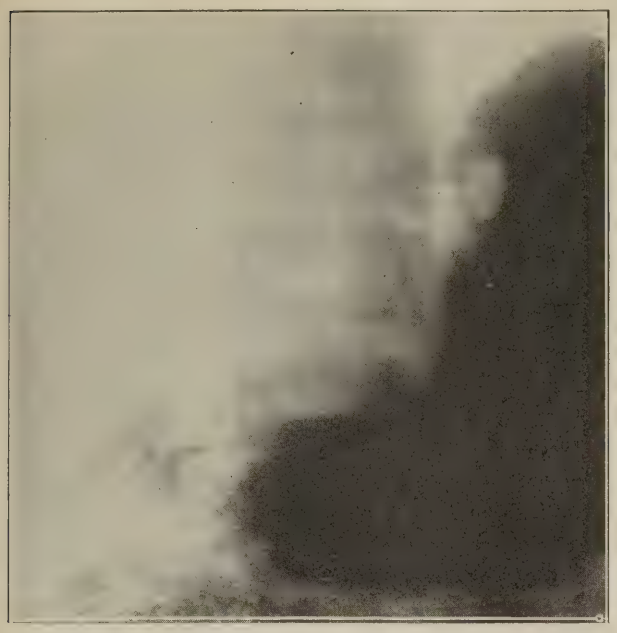

FIG. 5.—Total deformity of the cap due to ulcer.

FIG. 6.—Phthisis bulbi. The cap is shown as a narrow line a.

filling in various phases. It can easily be seen how one might be misled if an interpretation were based on the filled cap.

Pseudodiverticulum of the duodenum is occasionally encountered in ulcer (Fig. 4). This is due to ulcer formation and scar tissue retraction, and always occurs to the left of cap. This is in contradistinction to the true diverticulum, which occurs in the second portion of the duodenum, lies to the right of it, and is not associated or caused by ulcer, but is often congenital. It has no clinical significance and gives no symptoms unless it should become inflamed, and then it may produce an ulcer symptom complex. Also the true diverticulum may assume a very large size and present symptoms simulating pyloric stenosis.

Total deformity (Fig. 5) of the cap means ulcer in most every instance, but it is not pathognomonic; and the same may be said of the niche. Periduodenal adhesions from disease in surrounding viscera may produce marked deformity of the cap. But it must be borne in mind that a small erosion on the mucous membrane of the duodenum may give rise to extensive periduodenal adhesions. The importance of this fact is of concern to the surgeon. For every so often a patient is operated on for duodenal ulcer and the surgeon finds dense periduodenal adhesions, and after a separation of these he cannot feel any induration which indicates the presence of the ulcer, and the patient is closed up with the report that no ulcer was found. A variable time after operation, usually a few months, the patient again presents himself for examination and again duodenal ulcer is diagnosed. Reoperation again fails to reveal any induration to mark the site of the ulcer, and only after the surgeon incises the duodenum and inspects the mucosa does he find the lesion. This demonstrates the need for careful consideration on the part of the surgeon when operating on cases suspected of duodenal ulcer.

Phthisis bulbi is an occasional finding in duodenal ulcer. Here we do not see the cap, but merely a thin shadow of it caused by the adherence of some of the contrast substance to the mucosa (Fig. 6). In this type of cases the cap is extremely sensitive and irritable and immediately responds to any irritant, such as food, with violent contractions which force the irritant out into the intestine and so a thin line shadow is produced. The name of this phenomenon is derived from the analogous röntgenograph which is obtained in tuberculosis of the ileocecal region, but of course it is in no way related to tuberculosis.

The truly characteristic and pathognomonic röntgenograph of ulceration is the visualization of a niche on one of the curvatures of either the stomach or duodenum and an incisura on the same plane on the opposite curvature. Since most ulcers are seen on the lesser curvature, so must incisuræ occur on the greater curvature. So the finding of a niche on the lesser curvature of the duodenum and an incisuræ opposite on the greater curvature (Fig. 7) is absolutely diagnostic of ulcer, and no further evidence is necessary in coming to a conclusion. This cannot be said of any of the other deformities caused by ulceration in the duodenum, for any of them may be produced by other causes, and ulcer is diagnosed by exclusion, or by the consideration of other röntgen and clinical signs of the disease. It is true though that a deformed duodenum most frequently means ulcer.

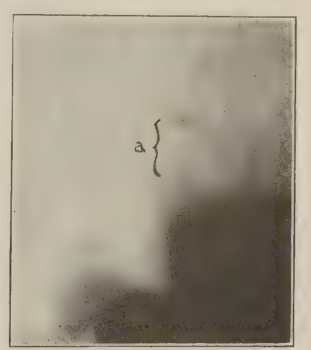

FIG. 7.—The niche and incisura type of deformity. The niche is seen at a, and the incisura at b.

In this presentation no attempt has been made to cover the subject completely, space does not permit it. But mention has been made of some of the frequent types of deformity that are encountered. The indirect signs of duodenal ulcer have not been men-

tioned. They are of the utmost importance, and are often the only röntgen evidence we have of the existence of the disease. Such signs are: gastric hyperactivity, gastric residue, colonic hypermotility, and other conditions. All the direct signs of ulcer have not been mentioned. The diminutive bulb sometimes caused by ulcer at the junction of the first and second portions of the duodenum, or the dilated bulb with delayed emptying, the socalled *dauer bulbus,* have not been discussed. In the last analysis the röntgen ray is not a conclusive means of diagnosis in this disease, except where we are able to demonstrate the lesion either by direct or indirect signs. At no time should the clinical picture be neglected. Fluoroscopy is of first importance in dealing with gastrointestinal diseases, and in a large majority of cases it alone is necessary; very often plates serve only as a matter of record and are valuable in following up a case. But on the other hand, we find cases where fluoroscopy gives us but little information, and plates must be relied on; this is particularly true of stout individuals, and those in whom the duodenum takes a position directly behind the pylorus.

In attempting to correlate the röntgenograph of the duodenum with the clinical picture, very often leads to what appears to be contradictory findings. A markedly deformed duodenum may give rise to but mild clinical symptoms, while a small niche may give rise to the most pronounced clinical symptoms. It must be remembered that only the uncomplicated ulcer gives the typical clinical picture of pain with food relief, night pains, and seasonal pains. The complicated ulcer gives rise to more or less continuous pain, no food relief, loss of appetite, etc. Also the röntgenogram cannot be taken as an index of the gravity of the lesion or the suffering of the patient.

It is true that duodenal ulcer exists which gives no röntgen evidence of its presence, or else misleading signs. What the explanation for this is we are not certain. But it is to be remembered that a small erosion involving the mucosa may give rise to a typical clinical picture, and yet give no röntgen signs in the duodenum or any indirect signs in the gastrointestinal tract. Also if the patient is free of symptoms at the time of the röntgen examination it is fair to assume that no spastic or irritative phenomena will be observed röntgenographically, for these signs depend on clinical activity of the disease.

It is interesting to call attention to the observations made by one investigator in Germany in the study of gastric ulcer. He employed the röntgen ray, and followed this up with gastroscopic investigations of each case. Then he proved either by operation or necropsy that the röntgen ray failed to show any evidence of an existing ulcer in thirty-five per cent. of his cases while the gastroscope did reveal the ulcer. If this is true of gastric ulcer, may we not assume that a similar number of duodenal ulcers are missed by the röntgen ray?

It is well to emphasize a few points in concluding. It has been shown that the normal duodenal contour changes with various degrees of filling, and that a filled duodenum may obscure an existing deformity, and for this reason a serial study of the cap is advisable. Also it has been pointed out that any deformity of the duodenum is suggestive of the presence of an ulcer, but is not absolute proof of its existence. That the indirect signs of ulcer are of the utmost importance, and that the niche and incisura type of deformity is pathognomonic of ulcer.

Thanks are due Dr. I. W. Held, of New York, for his kindness in permitting the use of some of the illustrations.

The Rôle of the General Medical Practitioner in the Modern Mental Hygiene Movement*

IRVING J. SANDS, M.D.
New York

Until a comparatively recent period of time, the average person showing conduct disorders or behavior problems not accounted for by physical disease was regarded, not only by the layman, but also by the general physician, as a lunatic, for whom the sole salvation was incarceration in an insane asylum. Little effort was made to understand the basis for the peculiar behavior of the patient, and the entire problem was regarded as a punishment inflicted by the Almighty upon a family for some mysterious reason. The family regarded the situation as a calamity and associated with it a sense of shame and disgrace which prevented them from seeking any help. During the past two decades, however, there has been an entirely different attitude assumed towards the problem of mental disease, so that at present abnormal conduct behavior is no longer regarded as a visitation of punishment from supernatural sources, but simply as disease processes which run definite clinical courses and for which there are etiological causes and prophylactic measures.

The general practitioners in medicine, who are usually the first to be called upon for advice in the management and treatment of mental diseases, have of late years been inoculated with the scientific attitude of regarding these mentally sick individuals as patients, and not as nuisances who tend to strain their relation to the patient's family, and who tend to upset the physician's general routine work. Whether or not the inoculation had proved successful depended largely upon the intelligence of the particular physician and his scientific attitude towards medicine in general. Fortunately the majority of physicians have always been ready to approve any measure that will be conducive to the recovery of the sick

*Read before the East New York Medical Society, November 24, 1924.

whom they are called upon to help; hence we are constantly called upon by the general medical practitioners to state briefly the nature of the different mental processes, to offer an explanation for their various courses, and, what is more important, to offer all available prophylactic measures.

The following cases will perhaps introduce the subject more vividly:

Case I.—David A., aged sixteen, was sent to me by Dr. S. with the following problem. For the past six months this boy had been acting rather peculiarly. He frequently would leave his high school and would find himself miles away from his school and home. Often he would have headaches. A few days before he was sent to me, he found himself in New Jersey, being unable to tell how he had got there, how long he had been there, and what had become of his overcoat and books which he had with him when he had started out for school.

This boy was of normal delivery, had normal infancy and development, never had convulsions in infancy. He was bright in school and entered high school at twelve years of age. He was sociable, well liked by his playmates and was regarded as an exceptional student. His parents were quite intelligent but economically rather stressed. David was well developed physically. He participated in athletics and was regarded as a wholesome, lovable fellow. Physically he showed an unusually precocious development; he weighed 175 pounds; his blood pressure was 125/65; heart and lungs were negative and there was no evidence of any physical disease. He showed, however, widely spaced incisors, rather short and broad nails, and a strong development of his secondary sex characteristics. When questioned about his peculiar behavior he said there was absolutely no reason that he could offer to explain his conduct. He said that for the past six months he frequently had headaches, intertemporal in position. Occasionally these headaches would be associated with peculiar colored zig zag lines which were in one side of his visual field and which would last for about three to five minutes. He could not account for his peculiar wandering spells. It was quite obvious that we were dealing with a case of epileptic equivalents caused by dyspituitarism. The intelligence of the boy, the occurrence of these peculiar spells as the adolescent period, and the physical evidence of dyspituitarism made us feel that we were dealing with a case of pleuriglandular disturbance, for which the basic factor was a disturbance of the pituitary gland. Our suspicion was confirmed by therapeutic measures. He was prescribed pituitary extract which he took steadily, and for the year that he was under our care he was free from any of his spells.

Case II.—M. M., aged sixty-six years, was sent to me by Dr. B. His chief complaint was failure of memory, difficulty in locomotion and difficulty in urination. His family history was negative. This man was native born, had a common school education, and was an optician by trade. He was always rather of a lively, open disposition; friendly and a favorite among the women. He married at the age of twenty-five and had five grown children. Except for a few attacks of gonorrhea he has been relatively free from any disease. About eight years ago he had a few dizzy spells and he consulted his physician. The latter informed the patient that his blood showed positive luetic infection. The patient was indignant over it and insisted that the physician was merely trying to enlarge his practice. For how could it have been possible for him to contract syphilis? In his own naive way he could not understand such a state of affairs. He had never associated with prostitutes and was always of clean habits. The fact that he frequently had sex relationship clandestinely with those who had frequented his place of business did not seem to make any impression upon him. Those women were, to his point of view, perfect ladies, and how could he insult them by even suspecting that they had syphilis? Upon examination this man showed irregular pupils which reacted sluggishly both to light and accommodation, tremors of his facial muscles, positive Romberg, unequal knee jerks and a tendency to a left Babinski. His spinal fluid showed 150 cells, four plus globulin, four plus Wassermann and a paretic colloidal gold curve. It was obvious that this patient was suffering from paresis.

Case III.—Betty E., aged nineteen years, was sent to me by Dr. J. because of her constant complaint that one of the instructors in the Teachers' Training School was urging her to run away with him. The history in this case is quite important. She is the second of a family of two children, of normal birth and of normal infancy. When a child she was rather quiet and obedient and gave the family very little trouble. She was regarded as a very good child. She was very different from her socalled boisterous, fresh sister, who would always get into mischief, and who had been a source of trouble to her family. When our patient was to be graduated from public school she displayed unusual interest in her books and in her studies and was regarded by her instructors and by her family as certain to meet with success in life. In high school also she was studious, was among the leaders of her class and would never go out with girls or belong to clubs or look for fine clothes as was the habit of her sister. When she entered training school she continued in the same routine, remaining at home, showing meekness and unusual obedience to her family and thereby being regarded as a favorite child. In her work at training school she showed good progress, but her bashfulness and shyness attracted the attention of some of her teachers. One of them told her mother that the child was not acting like the other normal pupils in the class. During the examination period she would lock herself in her room and would study until early in the morning. Such a procedure apparently met with the approval of the parents. For the past six months, however, her work became poor in school; she failed in some subjects and became quite a changed person; so much so that even her family began to realize that the child was ill. Upon advice of the family physician she was brought to me for my opinion. Physically and neurologically her condition showed nothing of significance. Mentally, however, she showed typical signs of a deteriorating psychosis for which nothing could possibly be done at that time. She was quiet, somewhat suspicious, but spoke clearly; she jumped from her seat and would look out from the window answering imaginary voices. When asked what she had heard she stated that about a year or so ago one of her teachers

in the training school started to control her mind; that he was constantly talking to her, and that he was now across the street urging her to run away from home with him. She stated that she was having sexual relations with him "through the medium of the air." She had ideas of reference and had belief in thought transference, reading of the mind, etc. She was actively hallucinating, was deluded and showed mood and emotional deterioration. This case of course was a definite, clear cut case of a dementia precox, paranoid type.

Varied and different as these cases appear to be, there is one basic factor common to all of them, namely, that there has been a break in the delicate mechanism which constitutes normal human behavior and that this break was caused by controllable factors that are found in the physical, instinctive and emotional makeup of the person and in the environmental situations that influence human conduct. Moreover, these factors even in their earliest manifestations were discernible in sufficient intensity to arouse the suspicion of a critical physician that the patient was suffering from behavior troubles which, unless immediately checked and corrected, would lead to serious mental illness.

What is normal human conduct? It is behavior that adapts the individual to his surroundings in such a manner as to be in harmony with his instinctive and emotional needs, and which will ultimately lead to normal biological existence. Normal behavior implies sound somatic conditions, adequate instinctive responses, proper modification of instinctive demands along socially approved channels, adequate emotional gratifications, and a proper correlation of these components in an organism so as to enable it to meet even unfavorable environmental situations.

Stating the problem, perhaps, in a simpler manner, normal behavior depends upon certain laws and principles which have basic fundamental anatomical, physiological, psychological and sociological factors, which should be known to every practising physician. Furthermore, the observation of these laws and principles lead to normal mental life and form the basis of the modern mental hygiene movement.

At birth the individual is endowed with certain hereditary traits, a definite anatomical constitution, and potentialities for action which are the instinctive component of his personality, and a definite tendency to derive a color tone of feeling, which composes the affective or the emotional side of his instincts. In infancy and in childhood his needs and cravings are practically fully satisfied and are met by the parents who tend to modify them to the socially approved standards of the environment in which the individual happens to be. At puberty there is a certain amount of personal responsibility encountered due to the enormous metamorphosis which has occurred not only in his physical, but in his emotional and instinctive life as well. This is really the beginning of the period of emancipation of the child from his parental control. In the period of adolescence this emanicipation from parental influence continues and the individual launches upon his own resources to meet environmental situations. At the end of this stage he is ushered into full manhood, free from parental control and expected to curb some of his own instincts and desires, and to meet situations fully on his own responsibility and to manage them in perfect harmony with his own personality and with those of the socially approved standards. Additional responsibilities are then facing him.

We see, therefore, that there are various stages in one's biological development which are likely to be interfered with and which result in abnormal conduct. The adequate handling of these factors really constitutes modern mental hygiene.

Mental hygiene must begin in the prenatal period. There is no doubt that the child should be given the privilege of having normal, healthy parents. The physician who knows that one of the contracting parties to a marriage is suffering from syphilis should tell that person that the offspring is apt to have hereditary lues unless active treatment is properly instituted. Such diseases as hemophilia and deaf mutism could be checked if persons suffering from such hereditary ailments were discouraged from bearing children. A large percentage of mental defects could be prevented if mentally defectives were discouraged from marrying. The pregnant woman should be given all the care that medical science offers in order that her offspring should receive a normal healthy somatic constitution. We are morally certain, though we cannot as yet postulate definite causal relationship, that infectious disease in the mother, in the pregnant woman, has detrimental effects upon the brain development of the individual. There are many who believe that epilepsy and mental defect in the offspring may result from the influence of toxins circulating in the pregnant woman.

It is important that obstetricians should hold in mind the future of the child. Prolonged labor is likely to put some undue pressure on the brain of the child, and may cause serious anatomical lesions in the brain which may lead to mental deficiency and to other neurological and even psychiatric conditions. There is no doubt that high forceps applications, especially in the hands of the untrained, cause considerable damage to the brain. With the modern trained obstetrician and the general application of aseptic measures in obstetrics, there should be little need for a high forceps application. One need hardly mention that the infant should receive the best possible care as far as feeding is concerned, and, in the present stage of our civilization, there is no excuse for the existence of rickets and other similar devastating diseases of infancy which leave a deteriorating impression upon the brain of the child.

Childhood is the golden age of mental hygiene. It is in this period that the personality is formed. The child mimics its adults. Many a neurotic mother has caused the development of neuroses in her children. Many a child will use illness as an excuse for not going to school or to gain some extra attention from the parents, because she has found that the mother has gained her ends from the father by feigning illness. A child should not be coddled too much. No child should be allowed to sleep with the parents. Many a boy has found it difficult to develop into independent manhood because of this practice, which caused an abnormal parental fixation. Many a parent has started a child on the road to constitutional psychopathic inferiority by satisfying everyone of its whims and fancies, by constantly lying to the

child in order to gain its obedience, by fighting the child's battles and thereby preventing its normal personality development.

On the other hand, some parents are too critical and harsh towards their children. They will never ask a child to perform a certain task, but order him to do it. Many a time they will not even wait to gain the child's attention before ordering him to do something, and the child is left in a frightened, panicky state. In order to escape punishment at the hand of an unreasonable parent, the child will lie in order to escape a trying situation. Making children obey needless commands, preventing them from participating in wholesome sports or games, deceiving them, showing favoritism among children, and inflicting undue and needless punishment, may cause feelings of discontent and rebellion, and may lay the foundation for delinquency and even criminality in later life. The child knows when he is wronged, and the feeling of resentment thus aroused may cause a conditioned antipathy for, and rebellion against, all other sorts of authority, so that later on the child may prove a troublesome pupil at school, and may even become a delinquent adolescent and a criminal adult.

We must, however, guard against the very good child; the one who does not show any initiative, who obeys his parents perhaps too well, who is overstudious, and who plays little, and who does not have any playmates. Such a child shows a peculiar negativism to all stimuli that immediately places him in the group of the schizoid personalities, which sooner or later will develop into a dementia precox type of psychosis. Such a personality, it will be recalled, was possessed by Betty E., Case III. It is really astonishing how many parents will tell the psychiatrist in discussing the personality of the schizophrenic offspring that he was "such a good boy"; that he had never given them any trouble, and that he had never "run wild" in the streets like the other children of the neighborhood. Poor parents. Little did they know that the very qualities which they were lauding were danger signals of an impending catastrophe.

There are children who display an undue amount of energy, who are overactive and overplayful, constantly on the go, apeing the other pupils, and who are also very bright and possibly precocious, who are apt to be the favorite of the teacher and the parents. Another group of children may show opposite traits. They are brooding, given to crying spells, who are rather slow in their physical and their mental activities. These two groups offer really an identical problem, for they represent personalities of the manic depressive type and are apt to develop manic depressive psychotic states when they are confronted later in life with difficult situations. These children should receive the best possible psychiatric care and attention, and they should be so managed that their peculiar personality traits will be checked before they gain complete hold on the growing children.

Still another group of children presenting considerable difficulty in management and requiring expert attention, are those sensitive youngsters who crave a good deal of attention, who cannot stand criticism, and who seek praise to such a degree as to even pursue deceitful methods for securing it. Such children have a lowered threshold to pain sensibility. This group must receive adequate training for they later form those adults who show the various forms of psychoneuroses, especially hysteria.

Occasionally in a child of apparently normal personality traits there may develop a neurosis or even a psychosis because of various situations at home especially in the relationship of one parent to another, or of parent to child. Unhappy marital relationship between parents not infrequently causes emotional upsets in children. The mother may take the child too much in her confidence and force the child to share with her all her cares and worries. Frequently an inconsiderate parent may precipitate even a psychotic episode in a child by assuming a tyrannical attitude towards certain problems. The following two cases illustrate the points under discussion:

Case IV.—Tillie S., aged fourteen, was brought to me because of nervousness, restlessness, crying pensaries and by private physicians for about five years.

Physically the child appeared to be a well developed and well nourished young girl showing no evidence of any somatic disorders. Mentally, however, she appeared to be quite sad, rather timid and cried easily. She said that her mother was worrying her. Her mother gave the following history:

She made good progress at school. The home environment, however, had not been favorable. The father, who was a barber by trade, paid little attention to his family. The mother accused him of infidelity, and there were frequent quarrels at home. The mother was given to crying spells and all sorts of hysterical manifestations. She would stay in bed for days. She took little Tillie into her confidence when she was about eight or nine years of age. She told her of the bad character of her father and of the suffering that the mother was enduring at his hands. She told the child that the only reason she would not leave her father was because she wanted to take care of the children. As Tillie grew older she began to share the family burden with her mother. When the mother would take to bed, in one of her hysterical fits, Tillie would look after the house and would prepare the food. She frequently would have to stay away from school. She would lie awake nights and worry about her mother.

The father, on the other hand, was kind and attentive to Tillie, and would shower her with gifts and other evidences of devotion. He, on the other hand, complained of the unkindness of the mother. Little Tillie was therefore torn between two conflicting emotions, and furthermore, at a delicate age, was burdened with grief and sorrow the nature of which she was entirely too young to understand. No wonder that she could not sleep nights, that she would have frequent crying spells, and that she began to do poorly at school. The dispensary physician told the mother that the child was in good condition and not to worry over her; but this did not alter the situation as far as the child was concerned. A month or so prior to her coming to me, she had had her first menstrual experience. She was utterly unprepared for it, and the sight of blood made her run with horror into the arms of her mother. The latter instead of explaining to her in a kind and gentle manner the significance of this phenomenon, told her that it indicated that the child was entering into womanhood

and that she, too, would probably share a lot similar to that of her mother. This information tended to intensify her dread and fear, made her more broody, and prevented her from sleeping.

This growing sensitive child was thrown into a severe neurosis because of ignorant, inconsiderate parents who forced her to share with them the misfortunes of an unhappy family life.

Of course, it is known to every physician that physical disease may be the basis for a neurosis in childhood. Cardiac valvular disease, anemia, errors of refraction, focal infection in teeth and in tonsils, speech defect, etc., may lead to abnormal conduct.

Case V.—Catherine M., aged eight years, was brought to me at the dispensary, the Neurological Clinic at the Brooklyn Jewish Hospital, by her mother, who stated that for the past six weeks the child had been doing poorly at school. She had failed in her subjects, would frequently cry in the classrooms and at home, could not eat, was somewhat constipated and would frequently cry at night, losing a good deal of sleep. When examined by me she showed nothing of a significance physically except a pallor of skin and mucous membrane. Intellectually she had an I. Q. of 110, and that was corroborated by her previous school work. Urine examination was negative. Blood count, however, showed a definite secondary anemia with hemoglobin of about sixty per cent. and a red blood count of 3,200,000. She was put on syrup of iron iodide and her mother was instructed to give her all the iron containing fruits and vegetables, and instructed to follow ordinary hygienic measures. The child improved remarkably under this treatment, so much so that she was able to return to her parochial school where she showed once more a normal poise and did well in her work.

The scope of this paper prevents me from further elucidation of the subject of mental hygiene in childhood. Suffice it to say that those children who show marked shyness, inattention at home or at school, sensitiveness to criticism, day dreaming, hypochondriacal fears, hyperkinetic or hypokinetic traits, sullenness, irritability, crying spells, twitchings in different parts of the body, poor motor control, etc., should receive proper and immediate medical supervision.

Adolescence brings with it great responsibilities for the parent, teacher and physician. This delicate period of development causes considerable introspection, and may prove a stumbling block for an individual possessing a delicate neural mechanism. The sexual development at this period may be fraught with considerable danger. At this stage of development, every girl should be told by her mother of the approaching change in her physical and mental make-up. Every boy should be told of the secret of life, and not be left to work out his own salvation, and learn of the mysteries of creation either in the barn or in the house of prostitution. It is amazing that parents should be so unwilling to discuss these problems with their children. Modern civilization, with the various billposters, suggestive literature, exciting movies, and other factors, causes hypersensitivity of the various emotional and physical reflex arcs comprising the psychosexuality of the persons and may play havoc with the mental life of the adolescent person unless the parent has prepared the child to meet these stimuli adequately.

Marked emotional crises may occur in the adolescent period and these may vary from mere transitory crying spells or periods of depression to irritability and resistance to all parental or school authority. The physician must be ready to recognize these fluctuations in mood reactions, and instruct the parents and teachers how to combat them. In this period of development many of the psychoses of later life may have their incipiency.

The physician must guard against such traits as seclusiveness, stubbornness, and excessive day dreaming, for they are danger signals of impending schizophrenia. The hyperkinetic, overtalkative, facetious, impatient, boisterous adolescent who shows a superabundance of energy and who has undertaken too many tasks and burdens must be taken in hand quite early, for in him there is likely to develop a manic phase of a manic depressive psychosis. The person lacking in energy, and in initiative, who is generally apathetic, and who perhaps is complaining of various somatic disturbances for which there are no anatomical causes, who tends to brood over insignificant matters, must be managed quite skillfully in order to prevent the development of a depression.

The emotionally unstable, hypersensitive, delicate person who is unable to stand the slightest criticism, who is constantly seeking approbation from his superiors is apt at this time to manifest real hysterical phenomena whenever its whims and fancies are not accorded immediate response.

At this period also all sorts of sexual fixations occur. All types of sexual aberrations may be entered into because of the unstable emotional condition that prevails at this period of life. Furthermore, some of the emotional and instinctive cravings of the individual may find expression in many overt antisocial acts, and in delinquency, especially along sexual lines. Other antisocial manifestations such as theft or robbery may result from adolescent, conflicting emotional states.

From the foregoing it is obvious that mental care of the individual should begin before birth, and continue until death. Every school should have a properly trained physician who should recognize incipient pathological mental reactions, and check mental disease. No high school should be permitted to exist without having a trained psychiatrist observe the pupils, for it is in this particular period of life that most of the pathological mental reactions find gross expression. It is far more important for the pupil to have a sound understanding of his own mental mechanism than it is for him to know when Julius Cæsar crossed the Rubicon, how to decline a Latin verb, etc. Every court should have attached to it a psychiatric adviser so that mentally sick people should not be punished for antisocial conduct over which they have no control.

The general practitioner, because of his close intimacy with the family of the patient, because of his constant observation of the family life and the family situations, because of his knowledge of the strong and weak components of the personality of the individual, and because he is the first to whom the family turns for help, is in a position actively to contribute to the modern mental hygiene movement.

Implants with Cannula in the Treatment of Atrophic Rhinitis

CHARLES CONRAD MILLER, M.D.
Chicago, Illinois

Atrophic rhinitis is a common condition which is spoken of in the most ancient of medical literature. The condition varies greatly. In some cases there is but slight odor, and dryness of the nasal mucosa with a few crusts here and there. In other cases the odor is extremely offensive, the tissues within the nose much atrophied, the passages wide open, and all surfaces covered with large crusts. As long as the condition has been known to the profession, it is strange that there is still a disparity of opinion regarding its causes. Some consider it merely secondary to sinus infection, while others look upon it as a primary disease due to a specific organism.

Despite investigations, there has not yet been discovered a specific organism by which the disease may be reproduced. Investigators have been able to grow in culture tubes a germ which produces, in the culture tube, the peculiar repellent odor of atrophic rhinitis.

In America many minor surgical procedures have been recommended in the treatment of this condition, but the work of American operators lacks that convincing element that the work of several continental operators posesses.

Lautenschlager has treated a large number of these conditions surgically. He holds that atrophic rhinitis is only the terminal stage of any rhinitis which is not arrested in its hypertrophic state, or which is not cured. Ozena is not therefore a special infectious disease, and there is no difference between the different types of atrophic rhinitis. All types of rhinitis have an inflammation as their point of origin, and their starting point is the interstitial tissue of the mucosa. From this they progress to the bloodvessels, which they obliterate. The vessels being obliterated, a degeneration and atrophy of the mucosa and of the bone follow. The mucosa no longer secretes in the ordinary way, the serosity is diminished and the secretion is thickened. Lautenschlager thinks that at will, a hypertrophic rhinitis can be transformed into one of the atrophic type, and vice versa.

All rhinologists have seen unfortunate cases where after too vigorous treatment, crusty rhinitis has developed with abnormally large nasal fossæ. These cases can be theoretically considered as different from ozena but practically they scarcely differ from it in regard to the reversal of Lautenschlager's affirmation, and his operative results are there to prove this possibility. It has been shown that injections of antidiphtheritic serum transform an atrophic rhinitis into a hypertrophic rhinitis but this change is not lasting.

In his operative technic, based on the foregoing conceptions, Lautenschlager insists on: 1. Suppression of inflammation. 2. To suppress any hindrance to circulation in the nasal mucosa. 3. To obtain a good circulation. 4. To prevent the exaggerated rôle of the secretion in the interior of the nose. 5. To obviate desiccation.

Lautenschlager accepts the view that ozena originates in an infection of the nasal sinuses in youth and that the pathological changes which occur in the bones and mucous membrane, the atrophy and the crusting are of secondary importance.

In his technic, Lautenschlager advances the lateral nasal wall toward the middle line, and removes the antral lining, whether macroscopic evidence of disease exists or not. In order to obtain a healthy lining to the antrum, he inverts as large a portion of the oral mucous membrane as possible into the denuded cavity and plugs for a long time so as to induce a thorough saturation of the bone. He also advises an inversion of Stenso's duct so that the resulting continuous flow of saliva will afford a further stimulus to the bone. The opening between bone and antrum is maintained which permits the saliva, which is only intended to moisten the walls of the antrum, to find its way once more into the mouth cavity.

Max Halle, in discussing the operative treatment, holds that as good or even better results than those obtained by Lautenschlager may be achieved by a modification of the latter's operation, which obviates much of the complicated technic and permits of a relatively simple aftertreatment. The inversion of Stenso's duct is discarded. The large fistula between the mouth and antrum is sufficient to insure that the gauze filling the antrum is kept moist by capillary action, while saliva is also forced into the cavity during the act of deglutition.

Halle operates with a local cocaine adrenalin anesthesia. Injections of a one half per cent. solution of novocaine with adrenalin are made in the mucous membrane of the septum, the floor of the nose, the lateral wall of the nose, and the mucous membrane situated anteriorly to the turbinals. The facial walls of the maxillæ are similarly infiltrated, and if possible block anesthesia is obtained by injecting the sphenomaxillary fissure. Operation may be started after an interval of ten minutes. The mucous membrane covering the medial aspect of the lower turbinal should be freshened without destroying any of the mucous membrane. Similarly treated is the mucous membrane covering the contiguous surface of the nasal septum. A vertical incision is made through the mucous membrane, covering the lateral nasal wall. This runs immediately in front of the middle and inferior turbinals and is carried down to the bone. The lower end of the incision is continued on to the floor of the nose which it crosses in a horizontal direction to end at the nasal septum immediately behind, and running parallel to the apertura piriformis.

The mucous membrane and the periosteum of the nasal floor are elevated with a fine elevator medially as far as the septum, and laterally to slightly beyond the border line dividing the floor of the nose from the lateral nasal wall. Following the line of the incision in the mucous membrane, a slender chisel of the West pattern is used to chisel through the bone,

avoiding splintering, the nasal wall is chiselled through at its junction with the floor of the nose. The sectioning is carried out beneath the mucosa, the chisel being inserted into the pocket formed by elevating the mucoperiosteum.

The mobility of the lateral nasal wall being assured, it is then displaced inward forcibly and *en masse* by means of a blunt elevator introduced into the antrum from the front. In doing this, special attention must be given to the upper or middle turbinal regions. If the antrum there appears normal on inspection, the lining membrane is not interfered with; but, if Lautenschlager's example is to be followed, it should be removed in its entirety, resecting a part of the margin of the aperture, if necessary.

After the lateral wall has been forced inward, it forms a sharp angle with that portion of the lateral nasal wall still remaining. Working through this opening, it is an easy matter to control the ethmoidal labyrinth; the same opening is also used in the insertion of iodoform gauze. This is employed to insure the continued medial apposition of the inferior turbinal to the septum, pending the formation of adhesions.

The gauze plugs should not be removed for five days, owing to the abnormal tendency of these patients to hemorrhage. Middle ear complications are usually only to be feared in the event of much sneezing being indulged in after the removal of the plugs.

The adhesions are left undisturbed for as long a time as possible, even should respiratory obstruction be complained of. It is a simple matter at a later date to divide the adhesions and eventually to lateralize the turbinal. Postoperatively the patients must continue douching of the nose for as long as judged necessary.

I have quoted at considerable length from the writings of Lautenschlager and Halle. In order to reduce further the severity of operative procedure, and at the same time to get the obstruction of the nose which they obtain by the extensive sectioning of the lateral wall of the nose, I have used in these cases implantations into the septum medially, and implantation into the turbinal tissues, and the tissues adjacent.

In this country simple operative procedures have been practised, such as injection merely of paraffin, or the implantation of a small amount of cartilage or bone under the septal mucosa, and surgeons have claimed very striking results from such treatment. At the same time in this country there has been no operator who can show a large number of cases, hundreds of cases in fact, such as can our continental surgeons, in which striking results have been secured in severe cases. It is for this reason that we must take more or less interest in the radical measures of continental operators. American surgeons who have suggested the mere injection of paraffin have claimed striking results from this treatment. However, we must not forget that they have not had large numbers of severe cases which have responded to the simple surgical measures they recommend. There has been a tendency in this country to attribute relief in these cases to simple blocking of the air passages. It will be noticed from the comments abstracted from Lautenschlager and Halle, that they consider the sinuses important factors, and drain the ethmoidal as well as the maxillary.

This phase of these cases is worth considering and if there is any evidence of frontal sinus involvement, it is advisable to pinch off the thickened end of the upper turbinals and insure drainage from this space, even when there is only a suspicion of ozena.

Blocking of the passageway, no doubt is important. With a view of effecting this, with less surgical trauma than is necessary in the Lautenschlager or Halle technic, I have used implants into the septal walls. Those American surgeons who simply insert a small piece of cartilage or bone taken from another patient in a septal resection, certainly do not block the passageway very thoroughly. Some operators inject paraffin under the mucosa of the septum. Paraffin, of course, may cause much more connective tissue proliferation than desired, and if placed in an inaccessible situation can make trouble.

Gutta percha is an agent which subcutaneously does not produce excessive irritation. It appears to be just about as insoluble as a metallic deposit and resists the action of the body cells indefinitely. Implantations in the septum may be effected by a very simple technic using a cannula and trocar. This old fashioned instrument can be inserted under the mucosa, pushed along between the septal bone or cartilage, and mucosa, forming a pocket. In this, the gutta percha may be packed as much or as little as the operator desires. To facilitate packing, I have cut a slot in the cannula and had soldered around it a flange. This makes it easy to drop into the cannula the gutta percha particles. With a blunt ram, these may be pushed into the pocket formed. This technic has an advantage over the original technic recommended by me several years ago, when I injected the gutta percha with screw piston syringes. Unless chemicals were added to soften it, it was necessary to work rapidly to prevent the gutta percha from hardening in the needle, but when it is cut into small pieces, and inserted in a cannula, the operator may be just as deliberate as he wishes.

If the atrophy in the bones of the nasal passage is very pronounced and we have very large spaces between the septal walls, and the atrophied turbinals, it may be well to insert the gutta percha implants into the lateral wall as well as the septal wall. In these cases, the insertion should be made rather high up, as far as the operator can conveniently see with good illumination, and fairly well back in the nose. After an insertion has been made above, the operator may make another insertion rather low down, the object being to insert the implant so that there will not be too much tension upon the atrophied mucosal layers. If there be too much tension, sloughing out from pressure would defeat the purpose of the implant. Implantations can be so placed within the nose, as practically to occlude the nose, but personally I have not felt that such technic was adequate in severe cases. Neither have I felt it necessary to open the sinus into the mouth, but by a process of displacement after incising, have made a free opening which gives good drainage of the sinuses and allows packing.

To open the sinuses freely, one should incise just below the level of the orbital floor, coming down to the floor of the nose. Such an incision enters the maxillary sinus.

This incision should then be continued along the

floor of the nose directly backwards, and in some cases it may be well to make a parallel incision above the inferior turbinals. The tissues formed by this flap may then be displaced easily, and the maxillary sinus entered with a large blunt separator.

If the mucosa gives evidence of disease, more or less curetting may be practised before packing is done. When a maxillary opening is of such size as to give free access to it, the packing may be inserted in such a manner that its removal is not particularly difficult.

Today the implants in greatest favor among surgeons are those of living tissues taken from patients themselves. Cartilage implants may be made through the cannula described, but much more convenient living tissue to obtain is that of the abdominal wall. This is easily obtained after injecting a two per cent. novocaine solution in the skin. Fat seems to be better able to resist efforts of the body cells to destroy it, if it is cut into small pieces. There is another factor in the implantation of fat which we may consider of some advantage. After it has been placed in a new position in the body, there is more or less swelling of it. This will increase the effects secured at the time of operation. When fat is used as an implant, the technic is the same as where the particles of gutta percha are used, except that the fat may be used in masses, just small enough to pass through the cannula.

32 North State Street.

Rhinitis

JACOB DALEY, M.D.
New York

Inflammatory diseases of the nose are the most common conditions seen in the practice of the otolaryngologist and therefore require more careful study and consideration than has been hitherto given them. The frequency of these conditions in specific fevers, infectious and exanthematous diseases, makes them important to the general practitioner. In order that the various forms of rhinitis be treated intelligently and effectively, an exact diagnosis clinically, pathologically and etiologically must be made. Frequently constitutional causes should be looked for and one can be guided by a closer study of the gross pathological picture seen in the condition. Operative intervention is a common form of procedure irrespective of the diagnosis and consequently this practice has a tendency to throw many good nasal operations into disrepute.

Rhinitis may be classified as follows:

A. ETIOLOGICAL CLASSIFICATION
1. Direct (bacterial)
2. Indirect
3. Reinfections

B. CLINICAL AND PATHOLOGICAL CLASSIFICATION
1. Simple acute rhinitis
2. Turgescent rhinitis (vasomotor)
3. Membranous rhinitis
4. Pseudomembranous rhinitis
5. Hypertrophic rhinitis
6. Hyperplastic rhinitis
7. Caseous rhinitis
8. Atrophic rhinitis
   a. Simple
   b. Due to suppurative sinusitis (Ozena)
9. Suppurative rhinitis

C. THE UNUSUAL RHINITIDES
1. Acute coryza of the newborn
2. Gonorrheal rhinitis
3. Diphtheroid rhinitis of the newborn

ETIOLOGICAL CLASSIFICATION

1. *Direct or bacterial.*—Many efforts have been made to isolate a specific organism with apparently little success. The difficulty lies in the fact that in the early stages of infections there are a variety of organisms, frequently without any one type predominating. As infection progresses, this picture changes and a predominating organism results but the identity of this organism is not constant in the different controls.

A mixed infection transferred to a healthy nose sometimes failed to infect and when infection did occur the mixed type of bacteria disappeared and a predominating organism supplanted it, and as mentioned, the predominating organism was not identical with the different investigators. Foster (1) says he has observed ultramicroscopic bodies and believes them to be the offending organisms because Berkefeld filtrates diluted to one to 10,000 have produced classical rhinitides and excretions from those infections reproduced the original symptoms. However, most all writers agree that the cocci group are generally the offending organisms.

2. *Indirect.*—Under this head we include a condition which is apparently an aborted cold and which is only a paretic state of the nasal mucosa. This condition may subside without infection or may go on to suppuration. This state of swelling represents the first stage of inflammation minus the presence of the offending organism. It may be produced by: a, an endocrine disturbance as is seen in children during fits of anger, sorrow, or crying; b, draughts or sudden changes of temperature; c, autotoxemias; d, irritants, either mechanical or chemical; e, obstructive lesions, i. e., deviated septa, hypertrophied turbinates; f, reflexes from eyestrain.

3. *Reinfections.*—This type represents the so-called chronic cold, the cause of which is often found in ulcerated gums, septic tonsils, adenoids and subacute sinusitis.

CLINICAL AND PATHOLOGICAL CLASSIFICATION

1. *Simple acute rhinitis.*—This is really a socalled cold in the head, an infectious and contagious disease involving a part or whole of the nasal mucosa, including the accessory nasal sinuses, the symptoms usually limiting themselves to the respiratory apparatus, but the remotest part of the body may be involved.

It may be due to a disturbance of local circulation by a sudden change of temperature or vasomotor nervous system disturbance, a local growth of bacteria which is enhanced by obstructive lesions, i. e., deviated septa, hypertrophied turbinates or growths, trauma, change of climate, chemical irritation, lack of proper clothing, shock, and exposure to draughts and colds. Another form of coryza is not due to infection but rather to irritation of the nasal mucosa from some metabolic condition. In some persons certain spices and alcoholic beverages will produce the symptoms of an acute coryza which will disappear in one or two days after the elimination of the toxic substances. In some anemic children with a tendency to rheumatism, sugar or egg albumen might be the cause of a never ending nasal discharge, the treatment of which is apparent.

Pathologically, at first the mucosa is hyperemic with a bluish, glassy, dried appearance. As soon as the second stage of secretion is reached, the mucous membrane is swollen and edematous and covered with a water secretion. The swelling of the mucosa of the turbinal bones obstructs the nasal cavities and causes difficulty in breathing. The inferior meatus is filled with a grayish mucus and interferes with expiration. Gradually the edema of the mucosa disappears, the amount of secretion diminishes and normal conditions are established in about three weeks.

The treatment of this condition may be divided into local and general. The purpose of the local treatment is to remove secretion and reduce tumefaction, produce good drainage from the sinuses and establish ventilation. The medicaments are used to promote reaction to inflammation. The ones usually used are cocaine and adrenalin locally, steam inhalations, postnasal irrigations with some mild alkaline solution as Dobell's solution twenty-five per cent. or Seiler's tablets.

Constitutional treatment in the acute stage consists of giving quinine, hot drinks, Dover's powder, hot mustard foot baths, rhinitis tablets, aspirin, phenacetin, caffeine and the use of cathartics. The use of a tonic containing iron and strychnine internally is an excellent measure. As the acute attack subsides, belladonna may be resorted to.

After the inflammatory condition has entirely subsided surgical removal of the obstructive lesions may be attempted.

2. *Turgescent rhinitis.*—In this form, we always have a swelling of the inferior turbinates with symptoms of nasal obstruction. The etiology may be the same as in acute rhinitis, but in this form a deflected septum is invariably found. The discharge is thick and mucoid in character and the turgescence eventually results in a permanent hypertrophy of the mucous membrane. If an obstruction is present around the middle turbinates, the retention of secretion causes a hyperplasia around that area.

The local treatment consists in the use of Seiler's tablets or Dobell's solution as a nasal douche. Post nasal irrigations of two per cent. warm argyrol solution is highly recommended. These irrigations are followed by the introduction of pledgets of cotton wet with one per cent. silver nitrate, along the septal surface of the inferior turbinates in both nostrils. After five minutes, the pledgets are removed and the nose is irrigated with a mild alkaline solution. Cauterization of the inferior turbinates is good in some cases. The electric cautery is preferable, although others prefer the submucous application of chromic acid to the inferior turbinates.

Surgically, it is important to perform a submucous resection in the cases having a deflected septum. Nevertheless, underlying constitutional disturbances must be looked for and treated accordingly in order to be sure of a permanent result.

3. *Membranous rhinitis.*—In this condition, a membrane is seen over the septum and the turbinates accompanied by severe inflammation. Usually some glandular involvement is seen. In about fifty to seventy-five per cent. of the cases, the Klebs-Loeffler bacillus is found, while in the others the streptococcus is seen. Clinically it is and is not diphtheria, but it is wise to consider it diphtheritic and treat it as such. What relation this has to diphtheria has not been definitely established. The local treatment is the same as in simple acute rhinitis.

4. *Pseudomembranous rhinitis.*—A membrane is seen on the inferior turbinates and the septum. On examination the exudate is found to be composed of fibrin, leucocytes, red blood cells and mucus. This condition makes one suspicious of diphtheria, which can be determined by a culture. Upon removal of the membrane, there is a tendency to bleed. The membrane may be so extensive as to cause a serious blocking of the nasal passages. The diphtheria bacillus is rarely found in this condition and therefore is not diphtheritic, although it is advisable to isolate the patient until otherwise proved.

The treatment consists of irrigating the nose with Seiler's solution or other mild alkaline solutions. If the membrane is very extensive, the excess should be gently removed so as not to injure the mucosa. In between treatments the mucosa should be well oiled with albolene containing one per cent. camphor and menthol.

Constitutional treatment consists in the use of tonics; general hygiene, diet and the intestinal tract should be looked after.

5. *Hypertrophic rhinitis.*—This condition is characterized by a hypertrophy of the mucous membrane of the inferior turbinates resulting in a partial stenosis of the nasal cavities. If a deviated septum is present, accompanied by a sinusitis, a hyperplasia of the nasal mucosa results due to irritating discharges. In other words, we may have a hyperplasia with a hypertrophy of the nasal mucosa and either one predominating.

The etiological factors here may be the same as in simple acute rhinitis and turgescent rhinitis.

The treatment is purely surgical and consists in removing the obstructive lesions. The cautery is contraindicated.

6. *Hyperplastic rhinitis.*—The characteristic thing here is the thickening of the nasal mucosa due to prolonged mild irritation by secretions from the sinuses and is frequently confounded with hypertrophic rhinitis. The mucosa microscopically shows an increase in the number of cellular and connective tissue elements; whereas, in hypertrophic rhinitis, the cells are increased in size due to overnutrition.

The cause of this form of rhinitis is chiefly due to the contact of the septum and the middle turbin-

ate, causing pressure resulting in a retention of secretion of the sinuses and eventually producing a sinusitis. The secretions are serous or mucus rather than purulent. Polypi usually develop later.

The treatment is essentially surgical and consists in removing the obstructive lesions. With this procedure, treatment of the sinuses are instituted if a sinusitis is present.

7. *Caseous rhinitis.*—This form of rhinitis is due to a foreign body in the nose which is usually wedged in between the turbinates and the septum surrounded by a mass of granulation tissue. Behind this mass exists this form of rhinitis. These cholesteatomatous masses become infiltrated with salts of magnesium and calcium forming rhinoliths. The cheesy material in the nasal passages emit a disagreeable odor. This is mostly seen in children and is usually recognized by a unilateral discharge with symptoms of difficult breathing, headaches, earaches and reflex phenomena.

The treatment consists of a cleansing douche, then cocainization of the nose preparatory to removal of the foreign body. The mass is removed with a spoon shaped wire loop, snare, forceps or rongeurs, depending upon the size and character of the foreign body.

8. *Atrophic rhinitis.*—This form gives a characteristic picture showing sclerotic changes of the mucous membrane and the underlying bony structure, with the presence of crusts and a characteristic foul odor.

Simple atrophic rhinitis is characterized by the involvement of the trophic nervous system and consequently the nutritive condition of the mucous membrane is impaired. The etiological factors are at times uncertain but it is frequently due to lues or tuberculosis. The treatment must be directed toward the constitutional cause if found and treated accordingly. Lues and tuberculosis must be eliminated and operative procedure avoided.

Every cause hitherto mentioned may be the etiological factor of atrophic rhinitis due to suppurative sinusitis. These factors produce a decrease of the normal circulatory properties of the nose due to inflammatory reaction and is followed by a formation of connective tissue. The functional processes are either impaired, perverted or entirely lost with the result that the true mucus producing elements are destroyed. The secretion becomes thick and inspissated, dry upon the surfaces and develop the characteristic crusts with the ozenic odor. This odor is due either to decomposition of the mucopus or the presence of certain microorganisms.

Treatment is not extremely satisfactory and if the sinusitis accompanying this condition is advanced, all treatment is apparently in vain. Surgical interference should be avoided as much as possible as it will tend to make things worse.

Local treatment consists mainly in intranasal cleanliness and particular attention should be given to the sinuses. The nose is best kept clean by the use of hot intranasal douches of two per cent. sodium bicarbonate solution a few times a day. For the removal of the crusts, an aqueous solution of ichthyol ten to twenty per cent. on pledgets of cotton packed in the nose is excellent. For stimulation, iodine, argyrol or silver nitrate may be used.

The treatment of this condition with scarlet red was described in 1913 by Joseph Jacobs but apparently the results were not brilliant. This treatment has been modified by making a four per cent. emulsion of scarlet red with quince seed as its base. It is found to adhere to the mucosa and favorable results are reported. Its antiseptic qualities inhibit bacterial growth, thus removing the fetid odor and by stimulating cell proliferation, it tends to restore glandular function. Preparatory to applying this, the patient douches his nose with Dobell's solution or sodium bicarbonate solution. Then the scarlet red emulsion is applied to the entire mucosa and is gently massaged with the applicator. These applications are renewed every other day and it is found that in many cases after the second application, the odor and scabs disappear.

Another method giving fair results is described by Benians and Hayton. Their treatment consists of copious applications of glycerine or glucose or both to the infected area of the nasal cavities and is mainly directed to the odor of the disease. A mixture of pure glycerine with addition of twenty-five per cent. liquid glucose is used and applied copiously to the mucous membrane several times a day. This is first done by the surgeon and subsequently by the patient at home. Irrigating and spraying with a ten per cent. aqueous solution of glucose and glycerine may also be tried. The aim of this treatment is to exploit the activities of such organisms as Staphylococcus albus, which is normally found in the skin and the infected area, to the detriment of the obnoxious coccobacillus of Perez. The bacillus of Perez is proteolytic, while the staphylococcus has a capacity for the fermentation of sugars. This is one factor on which this method is based. The other factor lies in the necessity for tryptic ferments to act on protein substrates in a slightly alkaline medium.

Injections of paraffin have been tried with varied results. Baumgärten reports favorable outcomes by the use of his method in nine out of twenty-five cases. He first cleanses the nose by lavage and under novocaine anesthesia he injects one c.c. of three parts of paraffin and one part of petrolatum, at one sitting. This he repeats at weekly intervals until sufficient narrowing is obtained. The sites for injection are the posterior part of the septum, inferior turbinates, lateral nasal wall and floor of the nose. Ciro Caldero uses white petrolatum, maintaining that this is preferable to the injection of paraffin because of its better tolerance and facility of technic. After preliminary treatment for five to six months consisting of nasal lavage with physiological salt solution followed by applications of one to five per cent. silver nitrate, or iodoglycerine or tampons steeped in bovine bile, he begins to inject the white petrolatum. He reports seven cases with excellent results.

Vaccine therapy has been tried, but apparently with poor results. Pure cultures of Coccobacillus fœtidus of Perez is used. Hofer, however, reports complete cures by this form of therapy and that the restoration was complete and normal. The normal condition persisted after a period of seven years. The use of Bacillus bulgaricus has also been tried but with poor results.

9. *Suppurative rhinitis.*—Suppurative rhinitis or nasal suppuration is really a symptom and not a disease. Pus in the nasal chambers is present in later stages of acute coryza usually accompanied by a purulent infection of the sinuses. It is also found in tuberculosis and lues of the nose and in the various exanthemata. The purulent discharge is seen in that part of the nose that is in relation with the drainage of the different sinuses. If the pus is in the superior meatus, it comes from the sphenoid sinus or the posterior ethmoidal cells; if the discharge is seen in the middle meatus, it may come from the maxillary sinus, frontal sinus or the anterior ethmoidal cells. It is therefore reasonable to assume that nasal suppuration is rarely a primary disease and in reality secondary to a diseased condition of the mucosa, bony wall of the nose or sinuses. This leads to another subject, namely, diseases of the accessory nasal sinuses.

UNUSUAL TYPES OF RHINITIS

1. *Acute coryza of the newborn.*—This is a rare form and the obstruction is caused by a swelling of the pituitary gland and the presence of thick secretions which the infant can occasionally expel. The nostrils are filled with mucopus which flows onto the lips and into the nasopharynx.

As the infant cannot blow its nose, this must be carefully seen to by its nurse. A few drops of boric acid solution and hydrogen peroxide will loosen up the secretions. Argyrol, or colloidal silver solution, four or five drops in each nostril twice a day is indicated. Adrenalin one to two thousand oily solution is used in persistent obstruction.

2. *Gonorrheal rhinitis.*—This usually affects the newborn, the secretions being abundant and appears as greenish yellow pus sometimes streaked with blood. The nostrils are filled with crusts, easily become ulcerated and the nasal obstruction is marked.

The treatment consists in softening the crusts with borated glycerine and the instillation of twenty per cent. argyrol and touching up with two per cent. silver nitrate.

3. *Diphtheroid rhinitis of the newborn.*—This form is rare and is almost always fatal. Examination shows the nasal chambers lined with a false membrane which may extend to and overwhelm the pharynx. The cervical glands are enlarged. There is an abundant watery, seropurulent flow constantly running from the nose, which excoriates the nostril and the upper lip. Death is brought about by the toxemia and inanition. A sudden apneic attack may end the patient's life.

By following the classification outlined and treating accordingly, the results obtained will be worth while. Care must be taken in selecting operative and nonoperative cases. A doubtful or borderline case should be given the benefit of the doubt and no surgical interference attempted until every other means to obtain a cure has been exhausted. If after that period no results are obtained, surgery should be the last resort.

CONCLUSIONS

1. In order to treat inflammatory diseases of the nose intelligently, an exact diagnosis must be made.
2. Operative procedure is positively indicated in turgescent, hypertrophic and hyperplastic rhinitis if obstructive lesions are present.
3. In treating rhinitis constitutional disturbances should be looked for as they may be the underlying causes.
4. In doubtful cases surgery should be the last resort.

Droop Shoulders in Adults

With a Report of Twelve Cases

JAMES C. WILSON, M.D.
Hartford, Conn.

In this paper there is nothing new or original; neither is there any apology for writing it. It is written in order that we may have brought to our minds again the simple and frequent cause of many of our more or less indefinite pains about the occiput, shoulder, arms and hands, especially those which seem more or less related to certain nerve distributions, such as writer's cramp.

In a study of the shoulder girdle we find imposed over the conical thorax what we have in no other part of the body; a considerable weight supported by no bony structure, the only bone connection to the rest of the skeleton being the clavicle which simply acts as a radius for the shoulder to swing on when it droops. The shoulder is therefore entirely dependent upon the muscle structure for support and this structure is clearly liable to become overtired and consequently overstretched and unable to perform its duties. This condition results in the drooping of the shoulders and with the clavicle as a radius the shoulder cannot swing backward or just drop but must swing downward, forward and inward. The effect upon the underlying structures is evident. If the patient is fat, the pressure upon the nerve trunks may be and usually is general, especially if the patient wears a high corset to push the fat up into the axilla. The tenderness over the subcoracoid bursa is almost constant. Pain is usually complained of about the elbow without any particular tender spots and the hands are subject to cramps which may or may not be painful. Numbness is a very common symptom and usually affects the entire arm and hand. In a thinner subject the pain may be confined to one cord. In these subjects the pain is more likely to be of a sharper variety and refer more definitely to certain nerve distributions. Pain between the shoulders in

the back and occipital headache are very common. Numbness along the distribution of the ulnar nerve is very common. There may be no pain in the arm but muscle spasm, which is manifested in writer's cramp or of spasm of any other one group of muscles. There may be no pain or discomfort due to nerve pressure and the distress may be entirely confined

Fig. 1

Fig. 2

to muscle strain, especially of the trapezius or scapular group or the pain may be confined to the subcoracoid bursa. The bursa has been little spoken of; we talk of the subacromial and subdeltoid bursæ and it is true that they are sometimes affected but the subcoracoid is a much more frequent offender. This is plainly evident from a study of its location and consequent liability to direct pressure especially when the arms are thrown forward as in writing, typewriting, stirring and many other occupations. The effect of droop shoulder upon the circulation is also very evident and very important, especially in the cases of rheumatoid arthritis which we see.

We are not accustomed to look upon a large, full busted woman as the subject of round shoulders, but I am inclined to believe that they are the most frequent victims. This is particularly true of cooks.

Pressure over the subcoracoid bursa in the shoulder will usually show tenderness and occasionally reflex pain to any part of the arm. Of course, all pains in the arms are not due to this condition, as witness the case of Dr. B. which he reported to me. The patient, with severe pain in the arm, was referred by him to Dr. C., with reference to the advisability of removal of tonsils. Dr. C. advised that the tonsils be left alone but also reported that the patient had a polypus in the nose which was infected and that pressure on the polypus with a probe caused a sharp pain to extend down the arm. Removal of the polyp was followed by rapid recovery of the arm.

Our treatment is simple. Remove the pressure by means of a simple shoulder brace and then depend on general rest and tonic treatment. The position in which the patient works may sometimes be changed and no other treatment needed. Again the shoulder brace may be worn only tight enough to act as a gentle reminder that the patient is drooping and she is able to hold herself without the active support of the brace or the overtiring of the muscles. This is, of course, the ideal toward which we work.

Case I.—Mrs. C., of New London, aged forty-two, married, with two children, apparently healthy and in good condition. When twenty-one years old she had what was called a shock. She was unconscious for several hours and thereafter for several weeks was unable to walk or use the right arm, although motion was not entirely gone in any group of muscles. Since that time she had been able to get about with frequent rest.

Three years ago she began to have pain in the back of the neck on the right side, occipital headaches when tired, with pain running down the right arm to the elbow. There was often cramp and numbness in the hand, and tenderness over the subcoracoid bursa. The patient had flat feet, and the knee jerks on the right side were exaggerated. Wassermann was negative. The patient was entirely relieved of pain in the back of the head, the neck and arm by the application of a shoulder brace.

Case II.—L. N., female, aged thirty-two, married. She had had pain for two years between the shoulders, especially when working with her hands; at these times her hands and arms would "go to sleep." There was no particular pain or spasm of any group of muscles. Pain at times was severe at the occipital origin of trapezius. A shoulder brace gave almost immediate relief.

Case III.—Mrs. W. S., aged thirty-nine, married, two children. She had a sharp pain in the left shoulder upon arising on the morning of December 3, 1923. Several months before had had the same condition in the right shoulder. She complained of pain between the shoulders in the back and extending into the occiput; extremely tender over the subcoracoid bursa. A sling was applied on December 3rd, and a shoulder brace on December 6th. Pain was relieved by the shoulder brace.

Case IV.—M. H., of New London, aged thirty-two, single, bookkeeper. He was in an automobile

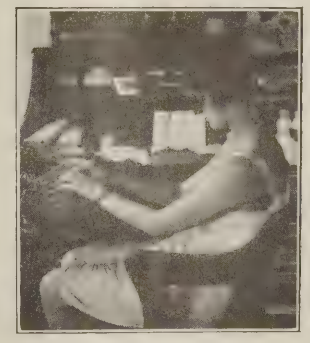

Fig. 3

Fig. 4

Fig. 3.—Position likely to cause subcoracoid irritation.

Fig. 4.—Position less likely to cause subcoracoid irritation.

accident three years ago, which was not considered serious at the time, but the patient failed to recover from pain in the back between the shoulders and in the lumbosacral region. Pain extended down both arms and the arms were numb. The head began to droop and a "bunch" appeared over the last cervicle

and first dorsal vertebræ. X ray was negative; nothing of cartilage or bone pathology was shown. There was tenderness over the subcoracoid and sacroiliac regions, both feet flat. General supportive treatment was applied. A shoulder brace relieved pain and discomfort in the arms, shoulders and neck. The "bunch" disappeared. The abdomen was raised and the general appearance improved.

Case V.—Flora R., aged fifty-eight, single, clerk, for about a year had had pain in her left shoulder with pain and cramps in elbow and hand. The condition continued to increase in severity until the patient was unable to sleep except for very short periods. There was great tenderness over the anterior aspect of the shoulder joint and subcoracoid, and pain on pressure radiating down the arm. A stereoscopic x ray examination of the left shoulder showed a calcified deposit apparently extracapsular in position, lying between the humeral head and the acromium process. A diagnosis of chronic subacromial bursitis was made. A shoulder brace was applied with complete relief of pain. The patient slept all night within one week and since had had no trouble except that after leaving the shoulder brace off for a while there would be a slight recurrence, but the shoulder brace always gave immediate relief.

Case VI.—Mrs. L., of Lee, Mass., married, aged forty-five, weight about 225 pounds, complained of no pain but had cramp in the middle finger of the right hand necessitating pressure with the other hand to relieve it. She wore a high corset which pushed the fat into the axilla. The corset was cut lower and a shoulder brace applied. She wore this shoulder brace for one week without a cramp. She thought she was well and left the brace off after one week, when the cramp immediately returned. She wore the brace for six months and had no further difficulty.

Case VII.—The patient, F. B., came to me in the winter of 1922-1923 complaining of pain in the right arm and the hand "going to sleep." He was thin but had always been well. He sat at a desk most of the time, sitting well back and very frequently having to reach to the left end of his desk for papers brought there by messenger as the left end of desk was nearest the door. There was very great tenderness over the subcoracoid bursa. The patient was cured by turing his desk around and sitting close to it which allowed him to keep the head of the humerus off the coracoid process and prevented pressure on underlying structures.

Case VIII.—This patient came into the dispensary complaining of being unable to sleep all night on account of the painful cramps in his hands. He was well nourished and aside from tenderness over the subcoracoid appeared to be in very good condition. A shoulder brace was applied and recovery was complete in three weeks.

Case IX.—N. B., a dressmaker, aged forty-four, came to me complaining of pain in the arms and hands with considerable muscle spasm in lower arm, also pain in back of head, neck and between shoulders. She obtained almost immediate relief from the use of a shoulder brace but the symptoms returned in from a week to three months after removing the brace when she was working.

Case X.—N. L., aged twenty-eight, a stenographer, had for nearly a year been troubled by cramping of hands when typewriting. This condition grew gradually worse until it became a serious handicap in her work. A shoulder brace gave relief and was worn for about a month when the patient was instructed to sit closer to her machine and had no more trouble.

Artificial Leucocytosis

BURR FERGUSON, M.D.
Rotterdam, Holland
United States Public Health Service

Reports of the control of the white cells obtained through the intramuscular injection of the salicylate of mercury and the intravenous use of novarsenobillon in the treatment of a number of infections, have been published in the *Lancet*, the Medical Journal and Record and in the *Franco-British Review*. These laboratory determinations were done by Dr. Seager Thomas, pathologist to the South Hants Hospital, Southampton, and it was found that after mercury, novarsenobillon and quinine bihydrochloride all varieties of white cells were increased in number, in about the same proportion as they are normally seen. So it would appear that each kind had its particular function in the resistance to infection.

Frequent counts of the blood of these controls showed marked differences in the days following the injection of mercury or novarsenobillon. For example, it was found that the increase after the injection of the salicylate dropped at the rate of about two thousand a day; that after the successive injections in any one control there was a rapidly diminishing power for the stimulation of the production of white cells, so that after the sixth or seventh injection, hardly any increase was to be seen.

On the other hand, in the counts following the increase after the arsenical preparation it was found that the white cells decreased in number at the rate of about five hundred a day, so that the count remained well above 10,000 during the week between injections. Also, it was learned that the body is much more sensitive to the arsenic, in that the successive injections are followed by about the same increase in white cells as is seen after the initial dose. Injections of the quinine were not continued, as it was found to be rather painful, and the controls objected to further study of the effect of this agent.

For the past nine years I have used the salicylate of mercury in various parts of the world with satisfactory results in the treatment of pyogenic infections, as is seen in furunculosis carbuncles, and small

infected wounds. Never was it necessary to give more than three injections, of one grain each, to rid a patient of the infection. For seven years of this time the drug was used empirically, and persisted in, because the infected patients were relieved.

Two years ago I called on Dr. Harry Simson, at that time pathologist of the Borough of Southampton, with the request that a white cell count be made, that one grain of the salicylate be given and another count be done in twenty-four hours. This was done. The count before the injection of the mercury was 9,000 to the c. mm.; twenty-four hours thereafter it was found to be 19,800. Other counts and injections were done by Dr. Simson in the Borough Hospital, and it was found in every case that an increase in the white cells followed the injection of the salicylate. In no case in this series was the increase found to be as great as that of the first control.

In the main, these injections were given by Dr. Simson to patients with chronic otitis media. At first some improvement seemed to be seen, the discharge of pus was increased and rapidly became less and more serous in character. Equally good results did not follow the succeeding injections. So it was concluded that this plan of treatment was not useful for such chronic infections. At this time it was not known that the tolerance was so quickly established, nor that the count declined so rapidly, as no further counts were done on the blood of these patients.

Through the good offices of Dr. Frank MacGee, medical officer in charge of the Atlantic Park Hotel for the detention and inspection of transmigrant immigrants to the United States and Canada, and Mr. Arthur Zorab, consultant, this plan of treatment was tried in the detained cases of trachoma. Improvement was marked after the first few injections, becoming less and less with their continuance. The usual local treatment with copper sulphate or cyanide of mercury was done in all these cases by Dr. MacGee.

When it was found that a tolerance was established after a few injections a rest was given these patients from the injections of the mercury, the local treatment being continued by Dr. MacGee. Five or six weeks later injections of the salicylate were again given, and again noticeable improvement was to be seen, which became less and less with each successive dose. About twenty-seven out of the thirty-one patients on whom this plan was tried were finally thought to be well and were permitted to embark for Canada and the United States, where they seem to have passed all inspecting officers as being cured of trachoma.

With the knowledge of the well known effect of the use of mercury in the treatment of syphilis and the observation of its effect in the treatment of trachoma, two facts seemed apparent in both infections; first, that the greatest improvement was to be seen after the initial doses; second, that the counts of the white cells showing the rapid establishment of the tolerance would seem to explain why so good an effect was not to be seen after the later doses; that the greatest good follows the greatest increase in white cells. Does not this observation agree with all the teaching and experience in the use of mercury, that it must be used in series of doses with rests between each series?

I became convinced that mercury was not a specific; that it had its effect, not from any property in itself, but solely from its power to stimulate the purely natural powers of resistance of the body, as represented by the only agents that may be seen in this phenomenon of resistance, the increased number of white cells.

In the attempt to extend the use of the white cells, the principle was applied in the treatment of asthma, eczema, chronic bronchitis, pyelitis, ulcer of the stomach, abscess of acute otitis media, influenza, ulcers of the leg, both the simple and the socalled varicose ulcer. Results were satisfactory.

While these results were being seen a friend had his usual recurrence of hay fever. On the belief that this infection might also be amenable to an increased number of leucocytes, he was given one grain of the salicylate of mercury. The good effect was immediate and lasted for six days. No counts of his blood were done but it had been learned that on the fifth or sixth day after an injection the white count returned to normal. He was given a second injection and the effect was not nearly so good as after the first.

In all of the cases mentioned above the striking similarity in the action of the first doses of mercury and the results that one sees following the use of salvarsan or its equivalent was apparent. So on the belief that novarsenobillon would also stimulate the production of white cells and probably do so better, he was given .45 of this agent. The infection was not cleared up at once but it became better and its further course was so modified that he had the best year he had had for fourteen years.

Five years ago I was in the service of the American Red Cross in Albania, where one might see many cases of æstivoautumnal malaria. On account of the discomfort following the use of the intramuscular injection of quinine, and having seen neosalvarsan successfully used in the treatment of tertian malaria in Alabama, it was tried in a number of cases around Tirana and Elbassan. Results were satisfactory. The temperature rapidly returned to normal and there was a rapid improvement in the symptoms of the infection.

Believing that all the three specific drugs derived their potency from the same cause, the stimulation of the production of white cells, a call was made on Dr. Seager Thomas, pathologist to the South Hants Hospital, Southampton. Dr. Thomas kindly agreed to do these determinations.

It would appear that the clinical effect of these drugs, as observed and reported by Dr. Seager Thomas, Mr. Arthur Zorab, chief of the Southampton Eye Hospital, Dr. Walter Elliott and myself, shows that they are not specifics. That their power comes from the stimulation of the natural forces of resistance. That whatever other parts of the blood may take part in this act, no one has yet seen them, and whatever they may be, the white cells are the only elements which may be seen, counted, and so furnish a useful indicator of the amount of the resistance and of the prognosis for the particular case. If the attending physician has a control of the forces of resistance, which may be very closely estimated by the increase in one of the elements of that resistance, the white cells, it is of little moment to him

as a clinician what other unseen and unseeable forces are at work. This is a laboratory problem.

On the recent visit of two U. S. destroyers to this port quite incidentally I heard of a case of furunculosis in one of the crew. These small vessels carrying no medical officer, the pharmacist mate was asked to bring the infected sailor to the dispensary. A young, powerful man was brought in, stripped and examined. Three active infections were found on his forearms, two on his buttocks, all of them discharging a slight amount of pus. His body, legs, and back showed many cicatrices of boils that had run their usual course, and many marks of incisions which had been made in the treatment of the *effect* of the infection. His history, recorded, showed that the condition had lasted for five years, during which time he had had all manner of treatment in naval hospitals, on shipboard, vaccines, and all of the usual procedures in such infections. The buttocks and a good part of the lower back were infiltrated with blood and it was altogether a very unhealthy skin. I gave him one grain of the salicylate and instructed the mate to give him two other injections at ten day intervals. The vessels sailed the next day for Copenhagen, where they were joined by the cruiser *Preston*. A letter was received from the medical officer of that vessel, Lieutenant B. W. Harris, a few days later, saying that he had seen the patient for the first time, who then showed a few rudimentary infections of the skin, that the boils that he had had were all cleaned up and that the infiltration of the skin was rapidly disappearing. After the third injection a letter from Gillette, the pharmacist mate, reported that the patient was apparently well; the infiltration of his skin had completely disappeared and he was feeling better than he had for a long time. There was no evidence of any luetic infection to be found in my examination of this patient.

In April, 1923, the nineteen year old daughter of a friend of mine in Southampton started showing an evening temperature. After several weeks' observation the attending physician, Dr. Fisher, made the diagnosis of a probable tuberculous infection of the apices of both lungs. The patient was sent to the Isle of Wight, where she spent the summer, having the usual treatment in the open air. She returned to Southampton in the autumn, running a temperature around 101°. About this time the results of the injection of salicylate of mercury in increasing the number of white cells was demonstrated. This was reported to Dr. Fisher and he decided to use this principle in the treatment of his patient who, at this time, was confined to her bed. After the first few injections the average evening temperature was brought down to 100° or less. There was no noticeable effect from the last of the nine doses that were given her in this series.

Beginning in February, 1924, she was given sixteen weekly injections of calcium. Dr. Fisher said there was no noticeable effect to be seen as a result of this agent. No further doses of salicylate were given. During the summer of 1924 the temperature remained well below 100° and she was allowed to spend all the daylight hours in the open air and on the few calls of observation that I made she seemed much better. However she continued to run a temperature.

In December last she developed furunculosis. Dr. Fisher sent to London for a stock staphylococcus vaccine. Weekly injections were begun, and about the second or third week Dr. Fisher noticed on the carefully kept chart that on one evening the temperature was normal. As she continued to have recurrences of the infection of the skin, the vaccine was continued. The next week there were two evenings with normal temperatures. So the injections were continued for about nine weeks when she had a normal temperature every day. Dr. Fisher continued his observation for a few weeks when he discharged her, cured. Would it not seem much more likely that this injection of a stock staphylococcus vaccine stimulated a production of white cells, rather than that the toxins of tuberculosis were neutralized by antibodies from such a source?

The annual report of the United Fruit Company of New York for the year 1924 has recently been published. In this volume is the report of the empirical use of the intravenous injection of a one per cent. solution of mercurochrome, in the treatment of a large number of infections, from ten to thirty c. c. being given in each case according to its virulence and the strength of the patient. Successful results were found in arthritis, cystitis, salpingitis, epididymitis, pericarditis, puerperal septicemia and pneumonia. The following conclusions are drawn:

1. That undoubtedly mercurochrome, properly administered, lowers the death rate in pneumonia.
2. That it hastens the crisis, and shortens the period of convalescence.
3. That practically no complications, such as empyema, result from this method of treatment.

Dr. van Heucelom of Rotterdam gave seven and a half c.c. of a one per cent. solution of mercurochrome, intravenously. The white cell count before injection was 8,000; in sixteen hours it was 9,500.

Dr. H. W. Nott, of Birkenhead (2), has reported successful results following enemata of permanganate of potash, one and a half grains to the pint of water, in the treatment of gastric ulcers, bacillus coli infections of the bladder, asthma, arthritis and a number of other infections.

Dr. Seager Thomas and I gave to a control with a count of 9,000 to the cm. one and one half c.c. of colloidal manganese. In twenty-four hours the white count was 21,000 to the c.mm. Such an increase would seem to be too great to be attributed to the irritation of the injection, so one might very naturally conclude that manganese has the power of stimulating the production of white cells.

I believe that further investigation will show that the administration of agents used in the treatment of infections is followed by an increase in white cells.

"Metchnikoff has insisted since the beginning of his studies upon phagocytosis that this process plays an important, if not the sole, rôle in immunity. He conceives that a true battle takes place between the cells and the invading germs. When phagocytosis is active and successful, immunity is the result. If phagocytosis is unsuccessful, the result is susceptibility instead of immunity." *Rosenau.*

The Influence of Physical Disorders Upon Behavior*

IRA S. WILE, M.D.,
New York

Behavior is an organic response to living. Its manifestations may be temporary or permanent. Constant behavior trends may be regarded as the unified habit patterns acquired through adaptation. Behavior in an acute episode is a temporary deviation from the usual norm. Behavior in this sense is conduct in its external relations. Evenness of performance, after frequent repetition, constitutes habit. The regularity of the heart beats, the pulmonary rhythm, the equilibrium of metabolism represent bodily habits upon whose chronicity physical health depends. When any organ of the body deviates from its accustomed course, its behavior creates an acute condition for which relief is sought.

Dermatitis may arise from the ingestion of various foods or drugs, from vaccinations or injections of antitoxins, from contact with poison ivy or sumach, or chemicals such as mercury, phenol, wintergreen and the like, or even from exposure to heat or cold, water or oil. Susceptibility to these various irritative actions varies in different individuals and in different areas of the skin in the same individual. The skin lesion may be directly responsible for numerous acute disturbances of behavior during the period of inflammation. The knowledge of a susceptibility to specific types of dermatitis may cause permanent alteration of trends of behavior. This simple illustration indicates one relation of internal and external influences upon bodily activity and psychic reactivity.

The interrelation of somatic conditions and psychic functions is recognized. The principles underlying their interdependence are not definitely established. Similar physical conditions affect different individuals variously, so that it is difficult to predict the results of physical disorder upon behavior. The same type of physical abnormality, occurring at different age periods in the same individual, is not necessarily attended by an identical series of psychic responses. There is always reason for caution in interpreting concomitant physical and psychic symptoms as having a real relation of cause and effect. Obviously malaise, torpor, irritability and delirium are related to febrile states, and various forms of infection, inasmuch as the psychic manifestations disappear with the decline of the physical symptoms. Certain types of infections, syphilis or intoxications, as with alcohol or caffeine, cause definite alterations in the physical, intellectual, emotional and moral status, but it is not possible to account for similar psychic dysfunctions by assuming such definite causations. Whether one is dealing with an acute or a chronic infection, a physical defect or a deformity, an injury or a dietetic deficiency, it is requisite to estimate the part each plays or may play in determining personality attributes. It is true, generally speaking, that the state of health modifies innate potentials or strivings, and that an improvement in physical status conduces to more favorable conditions for that indefinite integrated activity, termed normal behavior.

Behavior is not to be regarded as entirely bound up in problems of delinquency. It is to be viewed in terms of functional responses to the demands of social living. Physical inferiorities long have been regarded as factors in criminality despite the fact that similar inferiorities exist among a large proportion of the noncriminal population. Overdevelopment may be a serious factor in leading to antisocial conduct or it may be an entirely negligible factor. Generally speaking, exhibitions of irritability most usually present some physical basis for the lack of functional equilibrium. A considerable amount of mental dullness arises from physical causes. Defective vision, hypertrophied adenoids, impacted or abscessed teeth, chronic infections, abnormal endocrine function, and undernutrition variously handicap intellectual activity and conduce at times to such severe intellectual incapacities as to suggest feeblemindedness. Impaired hearing, arthritis, cardiac disease, or constipation, may result in emotional disturbances and intellectual limitations that combine to materially affect social attitudes and social behavior. On the other hand, primarily, psychic insults may result in a series of physical manifestations such as twitchings, paresis, paralyses, blindness, deafness, and almost all other syndromes identified with specific disease processes. Encephalitis presents the physical and psychic symptoms of a large variety of diseases both organic and functional, just as hysteria in its protean manifestations simulates a large variety of organic diseases.

In the interpretation of physical defects, or diseases, therefore, it is essential to differentiate the possible direct and indirect influences involved in reactions upon behavior. Malnutrition, for example, is a generic term, indicative of a state of health in which there are interferences with metabolism, attended by suboxidations and inadequacies in the nutritive values of the blood. The malnutrition may arise from an insufficient dietary, diseased tonsils, hookworm, lack of sleep, tuberculosis, syphilis, chronic nephritis, or from many other causes. If the malnutrition is accompanied by irritability which disappears after the removal of the cause underlying the malnutrition, it is probable that the malnutrition was a major factor in the behavior trend.

It cannot be assumed, however, that the removal of enlarged tonsils and adenoids, or a gain in weight will suffice to check or stimulate specific forms of behavior, even though the bodily improvement is indicated as a step in bringing about more normal physiologic functioning. Numerous instances indicate the value of antisyphilitic treatment in improving nutrition and in altering bodily function with attendant benefits upon behavior, but the treatment also frequently fails to produce the de-

*Read before the American Orthopsychiatric Association, New York City, May 9th, 1925.

sired alterations in behavior without numerous adjustments in the environment.

Encephalitis, with its many late manifestations, merits careful consideration because of our unfamiliarity with its effects upon character. It is a serious disease with profound alterations of personality. The frightful transformations which it produces are indicative of its severe effects upon the central nervous system, and especially upon those elements which determine capacity for moral behavior as opposed to moral judgments. There does not appear a parallelism between the severity of the physical sequelæ and the psychic deteriorations. Prognosis for behavior must be as guarded as that for a complete return to normal physical functioning. It is rare indeed to find a victim of encephalitis free from some abnormality of mental function. The consequent condition may arise from physical slowness and indolence to choreiform agitation, from drowsiness to stupor, from impaired concentration to feeblemindedness, from restlessness to almost maniacal excitement, from truthfulness and honesty to pathological lying and stealing, from slight carelessness in action and speech to exhibitionism and sexual excesses. Not infrequently, following the encephalitis, there is a predisposition to neurotic and hysterical manifestations. It is, of course, possible that the underlying constitution of the neurotic and hysterical might have led to these expressions, if the encephalitis had not occurred, and that the character changes incident to the encephalitis are merely expressions of an organic or functional weakness, partially responsible for the form of expression of the encephalitis. Inasmuch as this disease has come somewhat suddenly into the community, many of its milder forms have been unrecognized, and it is, therefore, important to investigate as to its presence in those individuals alleged to have shown marked and rather sudden changes in personality and behavior.

Fractures of the skull and even mild traumata of the head are recognized as causal in the development of psychoses. They are equally significant in the production of behavior disorders and are frequently overlooked in an estimation of causes responsible for abnormal conduct. In several instances röntgen pictures have disclosed scars of early fractures which had not been recognized at the time of the accident. It is important, in this connection, to comment upon the unwise practice of shortening the period of mental rest for those who have sustained cranial injuries. One must bear in mind the possibilities of epileptiform seizures, handicapping headaches, and hyperirritability as a consequence of insufficient aftercare for those thus injured. The trauma sustained should not be regarded as purely physical, because psychic results follow the physical concussion, laceration and hemorrhage. Not infrequently the secondary results of cranial injuries such as hemianopsia, deafness, and paralysis inject a new set of factors to condition behavior. These are as great an influence in determining behavior trends as many of the marked deformities, congenital or acquired, which play a part in lowering the moral resistances and in lessening general inhibitions. Strabismus, for example, which has occasioned taunting by school mates, has been the indirect cause of murder. Paralyses and hampering speech have been responsible for seclusiveness, isolation and suicide, as well as for begging and theft. Infantile paralysis with leg shortening has induced anxiety neuroses, depression, and paralyzant selfconsciousness as marked as that resulting from an obsessive fear following a psychic assault. Deafness, blindness, impacted teeth, and paralysis of the palate present instances wherein the psychic effects far outweigh the physical disability in hampering social living.

Recognizing the dire consequences of such physical disorders upon personality, it is apparent that malnutrition cannot be assumed to play too large a part in determining behavior. There are popular comments concerning the influence of foods upon character, but exactness in scientific knowledge is lacking with reference to the influences of especial forms of food. The effects of avitaminoses upon physical growth and functional development are slowly being revealed. Rickets, scurvy, beriberi, pellagra and similar dietetic deficiency diseases are yielding much valuable information concerning the relation of diet to behavior. McCollum, in his experiments with rats, has demonstrated that diet affects their emotions and dispositions; certain forms of diet, in fact, leading to practices of infanticide. It is possible, therefore, to conceive that malnutrition is not directly the conditioning factor so much as some specific lack of dietetic necessities. This is emphasized, for example, by the effects of iodine deficiency in the causation of goitre, the results of a lack of calcium, phosphorus, or iron in the production of various physical deficiencies. Careful studies of the effects of prolonged undernutrition in Germany, Austria and Russia might yield valuable insight into the influences of specific nutritional disorders upon the behavior of children, as well as upon their physical structure and function.

The secondary effects of physical disabilities upon behavior are to be interpreted in the light of their duration. There is a vast difference between acute, temporary, and curable disabilities and those which may be chronic in influence, despite some degree of amelioration, and those which are permanent and unalterable. Not infrequently the psychic effects of physical disabilities produce serious changes in behavior. This occurs, for example, among choreics and children with pseudoepileptiform seizures following accidents. The handicap that arises from interference with righthandedness, involving reeducation as a sinistral, may be productive of emotional disturbances leading to behavior types definitely disadvantageous. The tendency to convert natural sinistrals to dextrality is to be deprecated in view of the frequency with which the nervous strains involved interfere with normal selfexpression. Physical thwartings are no less significant than the interferences with conscious or subconscious choice. The relation between physical organization and conscious activity suggests the bearing physical limitation has upon psychic development, and the handicaps that are placed upon normal satisfactions arising from ex-

istent instinctive trends. The opportunity for mental conflicts between the ego and herd instinctive reactions is increased with emotional reactions that profoundly affect behavior. It is apparent that a speech defect such as stuttering, may be more devastating than the amputation of a limb.

Many alleged psychogenetic disturbances have their origin in physical factors. Some may be due to the effects of toxins, while others arise from biochemical alterations incident to metabolic or endocrine imbalances. Another set has their foundations in skeletal, muscular or visceral dysfunction from organic causes. One often finds vicious circles in which the original physical defect is accompanied by psychic reactions which, in turn, increase the physical incapacity, with a secondary increase of the psychic difficulty; these lead to manifestations of behavior in which the psychogenetic elements appear to be dominant. It is of the utmost importance, therefore, to analyze the physical constitution in terms of structure and physical function, before determining that the point of successful attack lies in the psychic field. A careful study of the sensory system, powers of coordination, the nature and extent of respiratory, circulatory and excretory disturbances is prerequisite for the interpretation of behavior. If too large a degree of attention is focused upon the endocrine systems, a considerable degree of information may not be given due valuation. An asthenia, attributed to hypoadrenalism, may prove to be caused by enlarged bronchial lymph nodes. Conditions simulating hyperthyroidism or hypothyroidism may be due to dietetic inadequacies and only the determination of the basal metabolism will serve to differentiate them. Hereditary variations of height, weight, and form indicate the danger in placing too great dependability upon the use of thyroid or pituitary substances for securing alterations in behavior, instead of educating for adaptations essential to normal behavior.

It is needless to point out the various overlappings of physical influences in the production of emotional reactions and the consequent social relationships. At the present time our knowledge of the functional factors entering into behavior is admittedly inexact and inadequate. Careful judgment and interpretation are required to estimate the direct influence of physical states upon mental function. Behavior is the resultant of numerous forces acting upon innate potentials. In the analysis of these forces, one cannot consider them individually, but in terms of their reciprocal effects. Certainly the foundations of life are contained in bodily organization. Whatever interferes with normal structure or function must play a part in the development of the total nervous system. The effects of these alterations are difficult to determine at the present time, but it would appear to be a basic principle, that every physical fact must be considered in relation to behavior. Whether one thinks in terms of the intellect, the emotions or social response, it is necessary to have an understanding of the potentials of physical abnormality and dysfunction in stimulating or inhibiting activity, either directly or indirectly.

The American Stomatological Movement in International Activities*

ALFRED J. ASGIS, Sc.B., D.D.S.
New York

I was going to write about the American stomatological movement in its relation to international activities, but due to the fact that some special and important problems have been discussed in the dental press and at various meetings recently, I think it advisable to concentrate on one of the most important and vital problems of dentistry in the United States today. This problem is the education of the dentist of the future.

First and foremost, the American Stomatological Association stands firmly behind the dentist. The aim and function of the association is to help dentistry to help itself. When we maintain the need of an M.D. degree for dentists, we mean the need of an M.D. degree for all dentists, not a special group or class of practitioners of our profession. We stand on the same platform as that of our European confrères. Stomatology has been victorious in Italy, and as a result dentists must have the M.D. degree to practise this branch of the healing art.

I have a letter here from Professor Piperno of Rome, the leader of the Italian stomatologists, which will give you a good idea as to how Italy feels with us in regard to this matter. It reads as follows:

To the officers and members of the American Stomatological Association, New York City:

The announcement of the establishment of a Section of Stomatology in the leading medical school in New York city has given me great joy. This is a very important step for the future success of the stomatological movement. "It is logical and useful that dentistry finally enters to be a part of medicine, as all other studies of the human body," said recently our greatest Italian clinician, Professor A. Murri. The Italian stomatological victory is now followed by the American movement. Of course, with pioneers and leading men as you are, success will not fail. My deepest greetings to all the officers and members of the association and to the editorial staff of the *Review of Clinical Stomatology*.

(Signed) Arrigo Piperno, Editor *La Stomatologia*.

I also wish to read to you a letter from Dr. J. Sim Wallace, of London, with whose work on stomatology you are all familiar:

At your next meeting, I should be very glad if you will convey to the members, on behalf of the English stomatologists, my warmest congratulations on the progress of stomatology in the United States, for which your association is doing so much. We are looking forward with the very greatest pleasure of seeing and meeting your representatives who are coming to England this summer.

(Signed) J. Sim Wallace.

This is the attitude of all our European colleagues to our activities, and when I speak of this problem of

*Read before the American Stomatological Association, New York Academy of Medicine, April 14, 1925.

medical education for the dentist of the future, I speak on behalf of the international stomatological movement, which represents twenty-eight countries, as well as on behalf of the American stomatological movement. Their problems are our problems. This problem arose when the term stomatology was introduced into medical literature in Germany in 1856-1867 for the first time.[1] The official recognition of the terms stomatology and stomatologist replacing those of dentist, dental art, dentistry, and odontology took place in Hungary in 1906.[2] In France, the authorities have recently substituted stomatologist for the old term dentist, pertaining to the regulations of dental service in the hospitals of Paris.[3] This question is now before the French dental surgeons throughout the whole of France. They, too, have to take care of the dentists in France, and it is from the joint cooperation between the stomatologist and the dentist in France that we hope the solution of the problem will come.

The problem is made more complex by confusing the issues involved. The situation can best be cleared by presenting the facts as they actually exist in the different countries. In France a law was introduced in 1892 to regulate the practice of dentistry and we have there the *chirurgien dentiste,* who has a diploma but is not an M.D. graduate, and the stomatologist, i. e., who is a physician who practises dentistry. In France the aim is now to have one degree, the M.D. degree, for all who practise dentistry. In Germany there are the graduate dentists or surgeon dentists (*approbierte Zahnarzt*) who are not M.D.s; graduates in medicine who practice dentistry but have not received the degree *Zahnarzt,* and the dental mechanic, the *Zahntechriker,* who practises dentistry without a diploma. In Belgium and in Switzerland a diploma is required. In England, on July 28, 1921, a law was enacted prohibiting the practice of dentistry by unregistered practitioners. This gave the dental mechanics, practising dentistry at that time, an opportunity to qualify and become registered and licensed dentists. Now we have there the graduate dentists or the licentiates (L.D.S.) and the non-graduate dentists (unregistered dental mechanics). There is also a third group, the stomatologists, who are graduates in medicine, practising dentistry. The dentists devote their practice to the care of the teeth, while the stomatologists devote themselves to the care of the mouth.

Here the oral surgeons advocate a medical degree for those who wish to practice the surgical branch of dentistry. At the same time they have given the impression that the dentists are to be identified as mechanics, and for them the D.D.S. degree is sufficient. While we believe that a medical training is necessary for the practice of surgery of the mouth, we also maintain that the medical training is equally important and indispensable for the treatment of the nonsurgical diseases of the mouth. We find, for instance, that in Germany the nonsurgical diseases of the mouth are under the care of men medically trained. And besides, socalled oral surgery is only one aspect of stomatology, which embraces every branch of dentistry. The consideration of the non-surgical diseases of the mouth must receive equally serious attention from the medically trained specialists of mouth diseases, the stomatologists or dentists. By that we mean, not merely a dentist with a medical degree, or a medical man with a dental degree, but what we aim at is a dentist, having had a medical education, a hospital experience, and what is most important of all, a medical point of view. We find many dentists practising the surgical branch of dentistry, who have a medical degree, but yet maintain and uphold the mechanical standard, and have the mechanics point of view.

We hold that dentistry should retain its unity, and that there should not be required for one group of dentists one standard, and for another group of dentists a different standard. One standard—a universal medical educational standard, the standard upheld and required of all ethical medical specialists in the United States. It is the standard of American scientific medicine. What logical and scientific grounds are there offered for the exception in our specialty? A medical educational standard should be maintained by the entire dental profession. By giving a small group of the profession this special equipment the cause of dental science will not be furthered. It will simply complicate matters and set up the surgical branch of dentistry on a medical level, and ignore the nonsurgical aspects of diseases of the mouth. This will mean a repetition of the error committed in 1839, when a duality of the healing art was established by separating dentistry from medicine.

The American Stomatological Association is not interested in protecting professional interests or professional groups; it is interested primarily in the protection of the interests of public health, and we believe that the dentist should have the opportunity and the facilities should be given to him in order that he may take his place as a medical specialist, equal to the ophthalmologist, rhinologist, and otologist. We maintain that the unity of the dental profession should be preserved and its autonomy, as a specialty of medicine, be kept intact. Only by unifying the standard in education and training and enabling the entire dental profession to obtain the necessary medical training will we be able to serve most efficiently the cause of public health.

Four Cases of Exophthalmic Goitre Treated with Insulin.—R. D. Lawrence (*British Medical Journal,* October 25, 1924) treated four cases of exophthalmic goitre with hyperthyroidism with large doses of insulin, using sixty to one hundred units a day. The insulin was well borne and caused no inconvenience. Two of the patients were greatly improved, one being practically normal on discharge from the hospital. In both the disease was uncomplicated and of less than a year's duration in women under thirty years of age. It seems unlikely that their improvement was spontaneous or caused by any factor other than insulin. The other two patients were not essentially benefited, although one gained much in weight and felt better. They were cases of toxic adenoma of the thyroid occurring in women of about fifty and of over a year's duration. The treatment was carried on under strict standard conditions of diet and close blood sugar control.

The Surgeon's Heritage and Outlook*

HUBERT A. ROYSTER, M.D., F.A.C.S.

Raleigh, North Carolina

Within the last quarter of a century the average life of man has been extended from forty-three to fifty-eight years. Analysis of the figures seems to show, on the one hand, a gain in the reduction of infant mortality, an increased saving of those under the age of five years; and on the other, an addition of eight years, which has occurred in the last twelve, among those who have had periodic health examinations.[1] May it not be claimed that modern surgery, too, has had much to do with man's longer lease of life? The period in which life's span has been lengthened corresponds closely with the rise of refined surgical science, which had its share in reclaiming many who otherwise were doomed to die. And the end is not yet. We are today losing but a small fraction of the early operative cases; it is our further aim to save the hundredth man, and to cut down the number of those needing surgical interference.

In spite of notorious prognostications to the contrary, progress in surgery has been made. Erichsen, an English surgeon of Danish birth, in 1855 voiced the feeling of many of his day when he said that the practice of surgery then had reached its climax and that no further advances in the art would be possible. How wide of the mark he shot, those of us now living can testify. Many more of us might now be tempted to make predictions but for the fate of Erichsen's view.

Generalizing is dangerous and prophesying is futile. Nevertheless, one may find profit in recalling past performances and in looking forward to future possibilities. Satisfaction may come from hearkening to the old refrains, that history repeats itself and that we can judge of the future only by the past. But are these sayings literally true? Much more delightful it is to believe that history betters itself, for we fain would hope that the conditions of yesterday are not good enough for the people of tomorrow. Moreover, if we are to judge the things of the future only from what has already happened, we shall more or less be living in the past and erecting our ideals upon bare experience. On the other hand, should we become fully pleased with the present, we shall likely feel no desire for improvement.

The science of surgery has been a late development. It was ushered in by the advent of anesthesia and antisepsis. It is now being brought to its highest degree by associated studies in other branches of medicine. Like all real progress, that of surgery has been subject to rules of action and reaction; sometimes it advances, sometimes it recedes, but always it looks forward; it throws aside what has proved to be false and picks up what may be true; it resolves not to guess, but to try; it inspires its followers to feel miserable today, if they have failed to learn something they knew not yesterday. The ebb and flow of the surgical tide has caused us to take up the old, if it were genuine, and to discard the new, if it were spurious.

But even the present proud position of surgery is no altogether new and sudden growth. Behind it is an ancient and honorable inheritance. Surgery as an art began with the dawn of recorded history, and even before; for prehistoric skulls show signs of operative skill and there have been preserved many specimens of primitive instruments used in the operations. In the earliest times cupping was done, abscesses were opened, cataracts were punctured and amputations were performed, at a time when tribal mutilations and ritualistic procedures were practised.

Tracing surgery back to its very beginnings, we find that in the earliest known records of man instruments made from sharpened stones, fishes' fins and teeth, from thorns and hard wood, were employed for various operations. The first known evidences of surgical procedures were derived from the Egyptians, who are not believed to have opened the cavities of the body, but who did perform circumcisions and other external operations. The Hebrews were versed in wound surgery, and were known to have practised Cæsarean section and excision of the spleen. The old Hindus, however, were ahead of all other peoples of their time in operative surgery. They were particularly adept in cataract extraction and plastic surgery, and brought their teaching methods to a fine state of artistic perception. Among the Chinese, surgery lapsed, for their religion prevented them

*The Jerome Cochran Lecture, delivered before the Alabama Medical Association at Birmingham, April 22, 1925.

[1]These statistics were obtained from the American College of Surgeons and the Metropolitan Life Insurance Company.

from drawing blood or scarring the body. Greek surgery was first chronicled in the grand epic of Homer, who placed the surgeon and his art on a lofty plane. Out of this background culminated the great Hippocrates, whose surgical knowledge and skill would have done credit to a later day. The Roman period represented by Celsus brought to notice the use of the ligature. Among the Mohammedans and the later Jews surgery did not go forward on account of the Oriental idea that it is "sinful to touch the human body with the hands" and of the injurious teaching that surgery "is an inferior and separate branch of medicine." The special feature of Arabian surgery was the introduction of the cautery instead of the knife for making incisions. An early Italian surgeon brought back the knife into general use, proving again, in the light of the recent movement to restore the cautery knife, that "nothing is so new as what has been long forgotten."

Coming to medieval times we find that the inferiority fetish caused surgery to be left in the hands of barbers and mountebanks, from which low estate it has been lifted up by devoted workers who have proved their faith. Look where you will you find that surgery has pointed the right way, has blazed the trail in any medical advance, but that it has always recognized its needful association with internal medicine. Attempts at separation of these two great branches of the healing art have left medicine helpless and surgery degraded.

There was a time when the surgeon operated under the direction of the physician who considered himself of a superior order and told the surgeon where and when to cut, where and when to rub or to bleed. Thus came into existence the barber surgeons, employed first to shave the monks and later to perform the offices of woundhealing and bloodletting. As they developed in skill and extended their field, the barbers were held in contempt by the few trained surgeons of the day and their practice thereby was limited. The elevation of the barber surgeon in France to the higher rank and the formation in England of the guild which finally grew into the Royal College of Surgeons constitute a familiar story.

With the revival of learning, the status of surgery once more came into its own. Marking this period is the beginning of German surgery, the full blooming of the Italian anatomists and the betterment of surgeons and medical schools in France. The real surgeons of the Renaissance were few and far between, but their influence was felt in their independent stand against the errors and superstitions of the time. The heroic Ambroise Paré is the dominant figure of this era.

Pushing further along, surgery proceeds through the next two hundred years hand in hand with the growth of literature, science and art. England and Holland led the way with physiologic and biologic discoveries directly bearing upon surgical practice. Anatomy was the principal topic of published papers and there are few references to surgery itself. The surgeon had not yet emancipated himself from his subdued station, though by individual effort some had adorned their art with respect. The latter half of the eighteenth century brought forth, in France at least, the recognition of the surgeon as the scientific and social equal of the physician. The King's illness and his cure by a surgeon secured the Royal decree in 1724 for establishing surgical professorships, for excluding barbers from practice and for creating standards. In England and Germany this restoration occurred much later and reached its ideal more slowly; the British surgeons, well educated in the arts and possessed of rare qualities as clinical teachers, presently adding great impetus to the growing art of surgery. The one man of this age who placed surgery on the solid foundation upon which it since has rested was John Hunter.

The modern era opens at the threshold of the nineteenth century with English surgeons in the lead and London as the mecca of the surgical world. Developing almost contemporaneously were a cluster of surgical stars in France and Germany and the first glimmerings of the art in America and Russia. The surgeons of this period were masters of their craft, bold in conception and fearless in execution. They did amputations and ligations, and performed plastic surgery with artistic skill. Individualistic study was giving way to collective scientific effort, and yet the highest type of surgeon was in the making, largely through the inspiration of Hunterian methods and pupils. Our own country can lay claim to the birth of surgery as applied to the diseases of women and to the perfection of surgical anesthesia. The names of the gifted pioneers who had a part in all these epoch making procedures are too well known even to need mention in this presence. But the greatest glory of the time—and perhaps of all time—goes to Joseph Lister, who introduced antiseptic surgery to a waiting world and rendered possible the development of surgical technic as we see it today.[2]

This running account of the evolution of surgery has dealt with races and nations and epochs rather than with individuals who have contributed to the cause. Three illustrious names were mentioned—Ambroise Paré, John Hunter and Joseph Lister. Concurring in the opinion of F. H. Garrison I hold these three to be the supreme surgeons of all the ages. It was the heroic Paré, valiant Frenchman, who fought for the privileges and the principles of surgery and paved the road along which the newer practice of the art might travel; it fell to the lot of the rugged Scotchman, John Hunter, to open the whole of nature to surgery by his clear thinking, his prodigious work of investigation and his profound delving into the subjects of physiology and pathology; it remained for Joseph Lister, the Briton, to crown the achievements of his predecessors by making it safe for all surgeons everywhere, then and now, to perform their marvelous works. It is to be noted that not one of these men was distinguished as an operator. Certainly they were possessed of mechanical ability, yet their fame rests upon other talents, and the impress they made upon the history of surgery, such as no others have made, was due to their higher attributes of superior judgment, common sense, persistent effort and ardent worship of truth. For us the lesson of their lives is that there have been many good operators, but few real surgeons. Operative skill, careful technic, manual dexterity are not at all to be decried, but alone they count for little in the balance

[2]I am indebted to Garrison's *History of Medicine* for most of the historical facts presented above.

against pathology, diagnosis and judgment. The careers of surgical geniuses of our own generation, some passed away and some now living, will prove eventually to depend for remembrance upon an enlightened wisdom, a broad knowledge of science and a keen capacity for administration and executive management, and not upon any unusually particular facility in their operating or any special method they invented.

Is it still unwise to predict? Shall we say with Erichsen that there are no new lesions to conquer, no more fields to explore? But what of the coming years? Along what paths will surgery proceed to its fulfillment? Will it be in the direction of more operating or less? Is the surgical profession to rise higher and higher in its ideals and practical results? Shall we become more and more separatists, acquiring superior skill in our mechanical gifts, apart from the study of the deeper and more serious problems of our science? These questions can be intelligently answered only by considering the present tendencies and applying our thoughts unto a vision of where these tendencies lead.

At the outset let us observe with satisfaction the increasing interest of surgeons in the correlated sciences. Even to the most practical of surgeons it is evident that, if he is to be a leader and not a mere hack, he must be versed in the fundamentals of chemistry, biology and physics. And in my view the greatest of his needs is chemistry; not that it is perhaps any more essential to his understanding, but because he has neglected its study and underrated its value. Chemistry is one of the bedrock sciences, in some respects the most important science. Its association with biology is intimate and the surgeon who prepares himself in biochemistry will reap his reward. In physics will be found the solution for many surgical problems to be worked out in the coming times.

It is my firm belief that we are going in the direction of less operating rather than more. Preventive surgery will have its day. But this day will come only when we shall have educated the people to the point of having necessary operations done promptly, so that late operations may seldom, if ever, be heard of. Unnecessary operations constitute the peculiar office of those surgeons who fail to understand that the highest aim of surgery may be the avoidance of operations. Never should the time come when the surgeon withholds his hand, if he can restore, readjust or remove some organ to save life, to redeem health or to relieve pain; but the habit of operating merely because it can be done, or because the patient expects it and even demands it, brings reproach upon our art and deadens him who yields.

Whether we shall see less surgery or more surgery, I believe we shall have better surgery, as we progress toward the lofty ideals now being erected in the name of standardized hospitals. Then, indeed, will practical results improve by leaps and bounds for, along with instruction of the people to seek advice early and often, and the schooling of the surgeon to study his cases, there will be a constant check upon operations to be done and effects to be obtained. More important by far than standardizing the hospital is standardizing the surgeon. There can be no escape from individual responsibility, from the choice for hospital positions of those who by talent and training are worthy to serve. Are we elevating our men as we systematize our methods? Are we not in danger of increasing the quantity of surgery without a corresponding improvement in its quality? Are we perhaps developing many surgeons of average, or even mediocre, ability instead of a smaller number of great capacity? Are we actually progressing? Not more than four months ago a noted pathologist, himself attached to a large surgical clinic, felt impelled to say that the progress of surgery had declined in the past ten years. By inference he attributes this decline to lack of knowledge of pathology before, during and after operative procedures. Emphatically he points out the small attention paid to necropsies in our surgical services and reveals many startling and unflattering circumstances. It would be difficult to set a time beyond which surgery has made no gains; but undoubtedly we are at a standstill in the matter of improvements now in sight. This does not mean, let us hope, that the limits of progress have been reached—only that something different must be unfolded, if we are to clear away the obstacles yet remaining in front of us. It may be old things coming back, rather than new discoveries growing up, to help us forward.

Our surgeon of the future will be deeply concerned with making plain the paths of surgery instead of endeavoring to complicate its ways. A severe simplicity, characteristic of strength, will pervade those who come to be greatest. Simple conditions in teaching, making it understandable, not obscure; simple, but efficient, technic in operating; simple methods of treating and dressing wounds—these will be the watchwords. Already we are getting away from putting things in to make it hard and are beginning to leave things out to make it easy. When we bring operative procedure to its irreducible minimum of simplicity we shall avoid innumerable sources of error. The management of wounds resolves itself into the avoidance of irritants, the gentlest handling of tissues, and the use of small dressings properly placed. The value of pressure in surgery is now being recognized as it has not been in recent years. Intermittent pressure, as in massage, is in constant demand; skillful bandaging, almost a lost art, has its virtues; the placing of pads or of the old sponge dressing on each side of a drainage opening or upon certain portions of a wound will often give ideal results. Plastic surgeons are laying stress on pressure for preventing dead spaces as against efforts for perfect asepsis with accumulations under the flaps. Altogether the tendency toward stripping surgery of its nonessentials is discernible. In part it is a reversion to first principles.

Dissemination of information in regard to diseases amenable to surgical treatment must be included in our plans of public education. Even as we teach methods of prevention in communicable diseases through public health agencies, so shall we see the need for spreading from the same source knowledge of surgical affections, avoiding the development of some and advising timely interference in others. By this means we may efface the "too late" verdict, saddest expression of our language. It is just as important to warn the people to have an operation on the gallbladder before jaundice appears or to have

the appendix removed before it ruptures, as it is to advocate means for the prevention of tuberculosis or advise vaccination against typhoid fever. Health boards of the future will come to see that preventive surgery is a part of their program. Deaths in early cases are so rare as to be inconsiderable; deaths in the delayed cases bring reproach upon our art. In no way can the mortality be more surely reduced than by teaching every person to seek surgical advice in time, if he needs it at all, and not to wait until socalled cardinal symptoms become terminal events.

I believe I see in the forthcoming days a resumption of the close association between the physician and the surgeon. Originally, as we have shown, they labored together, but the physician had the say and ordered the surgeon to operate under his directions. When the surgeon struggled successfully upward from his menial position, he took up the burden and the privilege of sharing the responsibility both in diagnosis and in treatment. The internist and the surgeon are now divided in work, but united in spirit, in the common purpose of curing the patient of his ailment. It is true the very name surgery means "handwork," but unless the head guide the hands, they were better never employed. The French definition of the physician as an internal pathologist and of the surgeon as an external pathologist suited the times, the middle of the last century, and suffices for today with both adjectives left off. Could we not best designate a surgeon as a skilled physician and something more? That added attainment is the ability to perform with zeal tempered by judgment all the necessary mechanical services which may contribute to the recovery of the patient. The day of the brilliant operator is done; the day of the genuine surgeon is here.

If there is to be less operating in the future (and there should be), shall we look for fewer surgeons? At present no dearth of surgical aspirants or surgical material seems to exist. Almost every medical student decides at least once in his course that he will be a surgeon. Worthy ambition! The practice of surgery to him is more spectacular, and its results more certain, prompt and evident than those of internal medicine. As the student becomes the practitioner and sees more intimately the different phases of work, he may observe (as in truth it really is) that there is more behind the scenes than he knew of, and that surgery is heavenly when all goes well, but the very opposite when adverse things occur. Some who have gone further along the road, if not of stout heart, may actually capitulate or wish they had had a chance to take in the whole medical field. The towering Murphy in his late years is known to have remarked that, if he had his career to go over again, he would be an internist. This, I take it, does not imply his discontent with surgery, but it represented his overwhelming thirst for new fields of knowledge, his broadening desire to go behind and beyond the mere lesions involved in his operations, his keen interest in the elucidation of the patient's problems.

The younger men in medicine will inherit so many questions for settlement and witness such interesting phenomena in their work of the near future, that they must needs be influenced less by matters of technic and actual operating than by studies in diagnosis and pathology. Urgent problems are pressing for solution and their final success will depend chiefly upon research, investigation and experimentation. The conquest of cancer is one of those problems. So far we have had few results, except those due to educating the public to submit to early examinations and early operations; and much good has been accomplished. But until we find the proximate cause there can be no consistent cure. Operative methods have gone far toward the checking of this dreadful disease, but nothing further may they accomplish in our ignorance of its nature and in our helplessness to diagnose incipient hidden lesions. Cancer undoubtedly will be conquered, but victory is not yet in the offing. The growing bounds of local anesthesia and the possible discovery of other general anesthetics suggest interesting questions. The thought that blood transfusion has been overdone, that it is not free from danger and that it has been useless for some conditions in which it has been widely employed, will put some mind to work upon this pressing matter. To say that radium has not quite met its expectations will cause further activity in this field whose portal we have just entered.

Again, will the specialists within the domain of surgery continue to increase in number? Or will there be a backward trend toward combining separate branches under general surgery? Only time and circumstance can answer. Specialism in general is not a new departure. All through the world's history there have been special men engaged in different fields of medicine and surgery. The Egyptians of old were said to have "had a specialist for every known organ and for every limb." This was an assumed specialism and so artificial and elaborate that it failed of its effect on scientific medicine. Without dispute modern specialties have come about through inevitable growth and they are a fixed part of our medical system. The subdivision of surgery into specialties was also a natural process, but it may be carried too far. The essential factor is that every man essaying to engage in a surgical specialty shall be a trained surgeon, capable of doing whatever may come in his particular work. Deficiency in such training was the cause of the original failure of the orthopedist to advance, but, when prepared men took up orthopedic surgery, it developed into a competent specialty. So much may apply to obstetrics and urology. Let those who would specialize seek first the kingdom of surgery and all the rest shall be added unto them.

Before closing with a final anticipation of what surgery may become, let me say first what I hope it may not be. Emphasizing the value and necessity of research, I would not, however, care to see surgeons developing into a company of purposeless experimenters, a gallery of empiric enthusiasts, extolling the opportunistic method of today and equally eager to adopt the new but untried theory of tomorrow. There can be no progress except by going along novel and, perhaps, unheard of paths; but in surgery such serious questions are involved as to preclude the use of processes that have not been tested and proven by science and by reason. Our art cannot be trusted to those who are inventing modes of mechanics, who are seeking to operate upon something, or whose idea of surgical research is to

perform theoretical procedures. Rightfully directed experimentation is absolutely necessary; the senseless sort is not to be tolerated. Pathological research is the most important of all.

I cannot help expressing the fear lest the practice of surgery degenerate into a business instead of a profession. This must not be. In this country, at least, our clinics and partnerships and groups are bringing us into financial combinations for the direct purpose of facilitating business. And this is all very well, unless the professional side be prostituted to mercenary ends, so that the business of surgery becomes the surgery of business. Are we drifting that way? Hear what a London medical observer, after a recent visit, has said of us: "The Americans are undoubtedly very able business men, and they seem to me to have made a business of the medical profession. There is little of the personal element which we know here. I cannot make up my mind whether this is desirable or not. The patient becomes a case, his wishes are not considered, and he is entirely in the hands of the particular surgeon he consults. Naturally, as in every business concern, the best business man gets into control, but it does not follow he is the best doctor. Again, from a business point of view surgery stands supreme, and the head of the clinic is always a surgeon who makes a final diagnosis, in many clinics pays a salary to other people as assistants, and is intolerant of any suggestion or alteration in his particular methods." Whether accurate in his comments or not, he is certainly frank. Do we recognize the outlines of the picture he paints? It is not the ordinary, sordid, professional commercialism which now concerns us; that is out of the question. The department store, ticket window, tag sale plan may be far more subverting to our ideals, for that it is the tendency of the times and receives common sanction. Is it admirable? A great surgeon, especially a surgical teacher, must develop an organization in order that he may care for the largest number of individual patients. While the master surgeons of the past generation were our equals and perhaps our superiors in manual dexterity, they could not begin to handle the number of cases looked after by the average surgeon of this day. The difference is that administrative experience was not possessed by the older men. Organization methods are essential. Our real bane is the growth of the salesmanship into surgery. Overproduction bids fair to stifle trade in America; overselling is worse, because it creates an unnatural demand. So it is in surgical practice. Salesmanship has no place with us; we have nothing to sell, we have service to render for a just consideration.

A vision of the future surgeon brings to light one who believes that he is not a "born surgeon," but, if so, he "must be born again"; who is surcharged with love for his calling, knowing that ardent desire is the one constant element of success; who realizes that he needs to be grounded in medicine and its allied sciences, giving his eternal allegiance to pathology; who finds as he goes along that good judgment is rather to be chosen than great mechanics; who learns that keeping physically fit is an asset to be sacredly nurtured; who recognizes his dependence upon training, first and last and all the time; and who, being conscious of his glorious heritage, presses on with optimistic courage to the outlook stretching on before him.

Extrapleural Thoracoplasty in Pulmonary Tuberculosis*

Report of Sixty Cases

WILLIAM H. THEARLE, M.D.
Denver, Colo.
Major Medical Corps, U. S. Army, Fitzsimons, Colorado

The frequent failure of modern sanatorium treatment to arrest the progress of pulmonary tuberculosis when in the ulcerative stage with its usually unfavorable prognosis; the impracticability of pneumothorax therapy in many such patients because of pleural adhesions, and the establishment on the Continent (especially in Germany) of surgical collapse as a definite procedure in suitable advanced cases of tuberculosis, are responsible for the recent merited recognition and increasing advocacy in this country of extrapleural thoracoplasty in chronic phthisis.

The aim of operation is to collapse mechanically one lung by a diminution in size of half the thorax by a paravertebral resection of various lengths of the upper eleven ribs in preferably two stages. The deribbed side of the chest requires support to minimize the paradoxical type of respiration, which always occurs after multiple rib resection. This, in our experience, is best accomplished by parallel adhesive straps over gauze pads, which at the same time permit gradual approximation of the rib ends until they are fixed by fibrous tissue, and later bony union.

Differences of opinion exist at present as to the method of anesthesia, the number of stages in which operation should be performed, the amount of rib that should be removed and whether resection should be performed from below upward or the upper ribs primarily removed, but the essential principle of the operation as developed and standardized by Sauerbruch remains; viz., extrapleural resection of the posterior portions of the ribs close to the transverse processes of the vertebræ.

Sauerbruch removes short segments (four to eight cm.) of the upper eleven ribs, and has repeatedly

*Published with permission of the Surgeon General, U. S. Army. The author wishes gratefully to acknowledge the hearty cooperation and assistance in this series of cases of the following officers of the Medical Corps, U. S. A.; Lieut. Col. E. H. Bruns (medical associates). Major C. R. Pollock, Captains D. G. Hilldrup, O. T. Kirksey and H. A. Bishop (surgical associates).

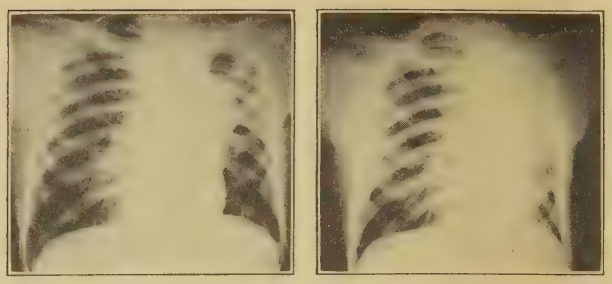

FIG. 1.—Case I. Before and after operation.

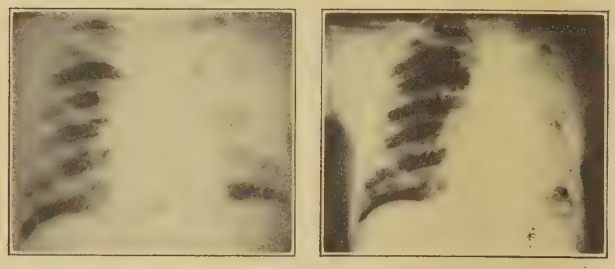

FIG. 2.—Case II. Before and after operation.

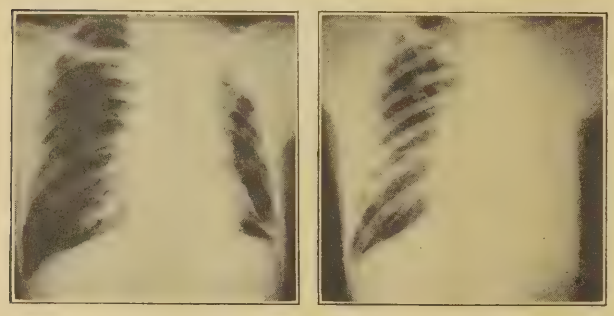

FIG. 3.—Case III. Before and after operation.

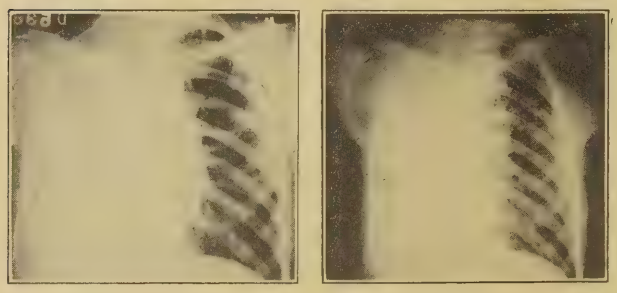

FIG. 4.—Case IV. Before and after operation.

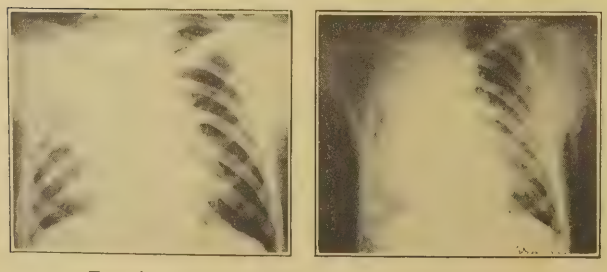

FIG. 5.—Case V. Before and after operation.

insisted that resection always be performed from below upward, as curtailment of the respiratory action of the lower lobe lessens the dangers of basal aspiration and complications. Brauer also collapses the lower lobe first but resects longer portions of ribs, especially beneath the scapula (ten to sixteen cm.).

Lambert and Miller, and quite recently Lilienthal, advise that thoracoplasty be performed from above downward, as the maximum cavitation and involvement in advanced tuberculosis are nearly always in the upper portion of the lung, which should be first collapsed to reduce materially the toxemia of the disease. They also believe that the unrestricted action of the lower chest and diaphragm permits easier coughing and expulsion of secretion from the lungs, and that there is thus less risk of lower lobe aspiration than by Sauerbruch's method.

Our experience with surgical collapse from above downward is limited to five cases, in four of which basal complications developed (aspiration and extension), which were probably due to interference with the respiratory function of the lower portion of the lung, when the upper lobe was primarily collapsed. We have not experienced to date an aspiration complication in the other thoracoplasties of our series, which were performed by Sauerbruch's method, and therefore fully agree with the latter as well as the majority of thoracic surgeons, that the lower lobes should always be primarily collapsed in pulmonary tuberculosis.

Thoracoplasty presents the same general indications as artificial pneumothorax. The patients suitable for operation belong mostly to the chronic fibrous group with cavitation, whose involvement is chiefly unilateral, when pneumothorax is impossible because of pleural adhesions, and whose better lung (with preferably arrested or slightly active upper lobe lesions) is considered competent to perform the full respiratory function without activation or extension of the disease.

Surgical collapse is also indicated in similar advanced cases for recurrent hemorrhages which pneumothorax fails to arrest, and in selected unilateral cases for acute pyopneumothorax promptly after its spontaneous development.

The advantages of artificial pneumothorax over thoracoplasty are: 1, it is a simple and relatively safe procedure; 2, devoid of shock and deformity; 3, collapse of the lung is gradually induced which permits readjustment of the altered thoracic contents with little danger of aspiration, and 4, the collapsed lung can be allowed to expand in event of the development or extension of lesions in the better lung.

Thoracoplasty possesses the following advantages over air compression: 1. Its immediate permanent collapse influences the course of the disease more promptly and definitely, as the degree of lung collapse varies constantly with artificial pneumothorax. 2. The patient is spared the long siege of medical supervision with its many refills necessary by the air method, which in time is not uncommonly associated with serous or purulent pleural exudates, and the serious complications of spontaneous pneumothorax and air embolism. 3. Lastly, it obviates the not infrequent occurrence of reactivation in an expanded lung after apparent cure by pneumothorax therapy.

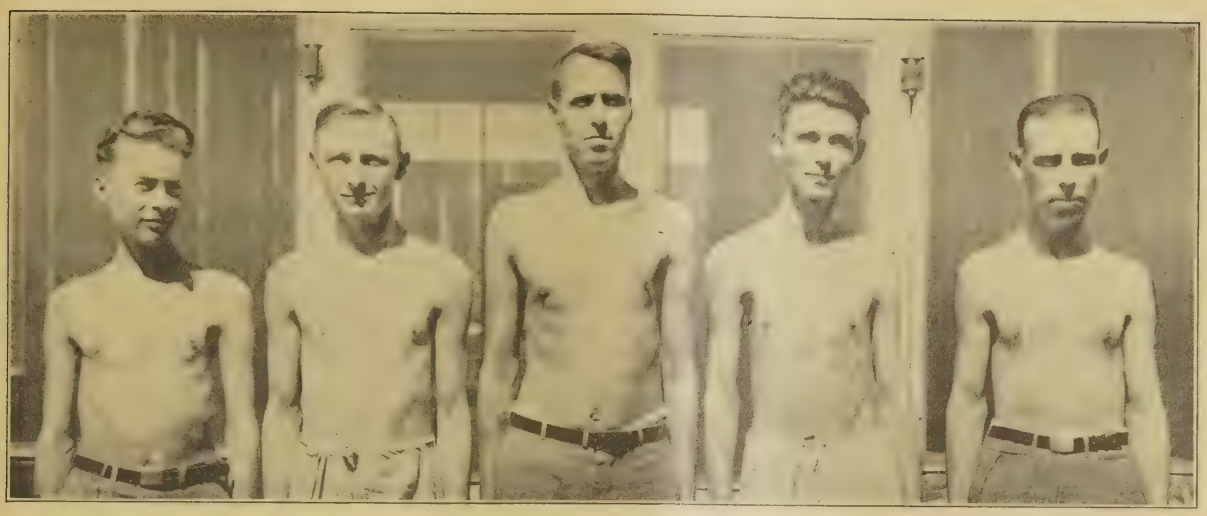

FIG. 6.—Cases I to V (left to right) after operation. Anterior view.

Preoperative measures do not differ from those in vogue for other major surgical procedures, except patients must empty secretions from cavities by posture preceding operation to reduce the danger of sputum aspiration to the minimum. The condition of the better lung and cardiovascular system determines not only the suitability of patients for operation but directly the operative and late mortality.

A single stage collapse is associated with a stormy first week convalescence and a relatively high mortality, due to the sudden marked change in relation of the thoracic contents incident to this extensive procedure, which warrant its performance only in very exceptional cases. A two (and occasionally three) stage Sauerbruch collapse of ten cm. rib resection, with its comparatively low mortality, is in our experience the most suitable method of thoracoplasty for the majority of cases of pulmonary tuberculosis. A wider resection of the Brauer type will usually be required to secure the complete collapse necessary in many patients with extensive cavitation throughout one lung and for pyopneumothorax cases, as well as those of large stature.

Phrenicotomy tests the effect of additional work on the better lung, gradually adjusts the thoracic viscera for the consequences of thoracoplasty, and probably reduces the danger of aspiration; it can be advantageously employed preliminary to surgical collapse in the majority of cases.

Our results in this series of sixty thoracoplasties, eight of which were in females, are as follows:

Disease arrested	30 per cent.
Improved	25 per cent.
Mortality	18 per cent.

Sauerbruch in a series of seven hundred cases reports thirty-nine per cent. cures, twenty-seven per cent. improved, ten per cent. unimproved, four per cent. operative, and twenty per cent. late mortality.

The following five case reports with röntgenograms and photographs illustrate the class of tuberculous patients and surgical procedures of this series of thoracoplasties:

CASE I.—Male, aged twenty-five, tuberculosis five years, active lesions both lobes left with six by eight cm. cavity upper lobe and inactive right upper lobe. Sputum one half cup a day. Two stage left thoracoplasty February 17th and March 20, 1925 (resection one cm. first, seven cm. eleventh, and ten cm. intervening ribs). Lung well collapsed. Patient ambulatory with slight cough and sputum, chiefly mornings;

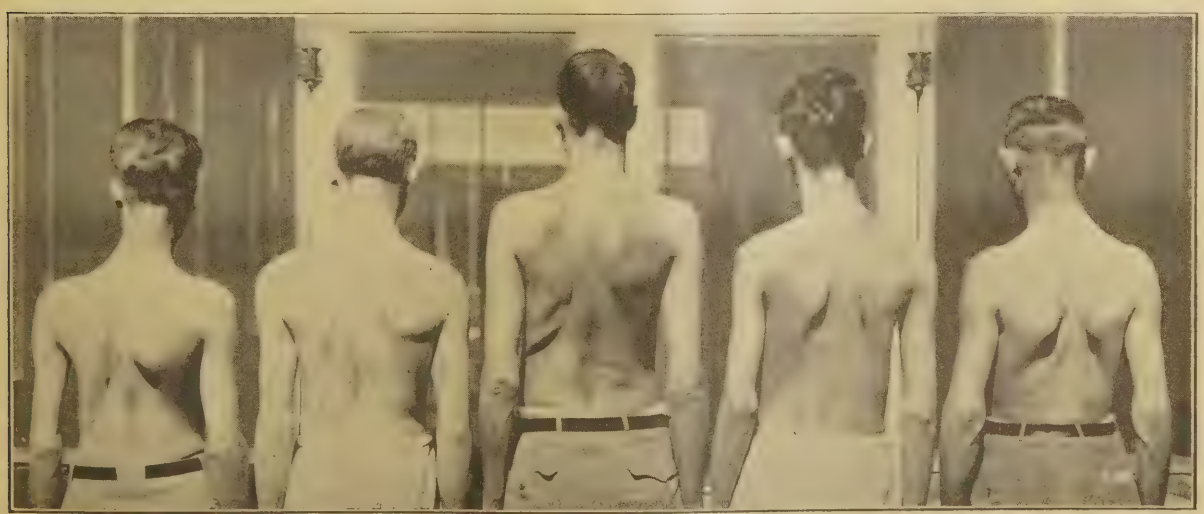

FIG. 7.—Cases I to V (from left to right) after operation. Posterior view.

gaining in weight and improvement in condition has been marked.

Case II.—Male, aged twenty-six, tuberculosis one year, active lesions all lobes left with five cm. cavity upper lobe, inactive all lobes right lung. Frequent hemorrhages of moderate degree. Sputum one third cup a day. Left phrenicotomy November 24, 1924, and two stage left thoracoplasty December 15, 1924, and January 2, 1925 (resection 1.5 cm. first, seven cm. eleventh, and ten cm. intervening ribs). Cavity obliterated and lung well collapsed, no cough or sputum for five months; patient gained fifteen pounds in weight; disease arrested.

Case III.—Male, aged thirty-six, tuberculosis three years, active lesions both left lobes with cavity upper lobe, and inactive right upper. Sputum one cup a day. Induced partial pneumothorax one year ago with slight temporary improvement and small serous pleural exudate. Two stage left thoracoplasty January 6 and April 9, 1925 (resection 1.25 cm. first, six cm. second, 7.5 cm. eleventh, and eleven cm. other ribs). Long interval between stages was due to serum in upper portion of operative wound which delayed healing. Lung well collapsed. Patient now has gained ten pounds in weight and lesions are apparently arrested.

Case IV.—Male, aged twenty-five, tuberculosis two and one half years, active lesions all right lobes with extensive multiple cavitation, slight scattered activity in upper left lobe with small apical cavity. Patient in poor condition with toxic myocarditis and disease a little too advanced for thoracoplasty, but as right lung was practically destroyed by cavities and fibrosis, and left was performing respiratory function, a two stage right thoracoplasty was performed April 17 and May 13, 1925 (twelve rib resection—1.25 cm. first, five cm. twelfth, 7.5 cm. eleventh, and ten to twelve cm. other ribs). Patient now ambulatory with slight cough and expectoration, and his early marked improvement makes us hopeful that a brilliant result will be obtained in this case.

Case V.—Male, aged twenty-four, tuberculosis ten months, active lesions upper and middle lobes right with cavity upper lobe, inactive right lower and left upper loves. Several hemorrhages (forty-five to 175 cm.) last summer. Sputum one cup a day. Two stage right thoracoplasty November 7 and 21, 1924 (resection 1.5 cm. first, 7.5 cm. eleventh, and ten cm. intervening ribs). There has been no cough or sputum for the past three months. The patient has gained twenty-two pounds in weight, his condition is extremely good, and the lesions are apparently arrested.

Congenital Cleft Lip

THOMAS F. MULLEN, M.D., F.A.C.S.
Pocatello, Idaho

With the increasing refinement of surgical technic and a keener appreciation of the varying resistance of the tissues, those interested in the question of reparative or corrective surgery are no longer content with moderate results, but seek to attain perfection from the anatomical and physiological, as well as the cosmetic viewpoint. Frequently the parents, or those interested in a child who has a cleft lip, are occupied entirely with the cosmetic aspect of the deformity and the many poor results following operation are testimony to the fact that surgeons do not always have a complete grasp of the entire problem or of the difficulties of its solution. It is the duty of the surgeon to bear in mind the fact that the lips and the nose have definite physiological functions, which are largely dependent upon anatomical integrity. In the correction of these malformations it is, therefore, not only a question of closing an unsightly gap in the features, but of doing it in such a manner as to restore the function of the parts with their relation to mastication, deglutition, phonation and respiration. In addition, the method of repair must be planned so as to minimize visible scars, give flexibility, fullness and length to the lip, and to restore symmetry of form and equality of size to the nostrils. Frequently an otherwise excellent result is rendered unsatisfactory by a slight flattening of the nostril, a difference in the size and direction of the apertures, or a break in the continuity of the vermilion border. Sometimes the fact that a lip has been operated upon is rendered obvious by the contrast in the appearance of the mouth during repose and activity, showing itself in the blanching of an old scar or in flattening or rigidity of the lip during conversation or the play of the features. Most often the final result is determined at the primary operation and while it is possible to correct unsightly scars satisfactorily, deformed nostrils and a notched vermilion border, the result is never as perfect as it would have been if the first operation had been done properly.

The deformity of the nose varies in nature and degree with the extent of the cleft in the soft tissues, and is greatly modified by a concomitant malformation of the underlying bony structures. It is moderate in simple, unilateral clefts of the lip alone (prealveolar clefts), in which, although the cleft is of variable length, there is always a deficiency or absence of the muscle tissue between the upper extremity of the cleft and the floor of the nostril, and more or less unshapeliness of the aperture. In this type the nasal ring is complete but the nasal orifice is broad and flat, and there is a small, hollow area consisting of attenuated tissue between the nostril and the upper end of the cleft (Fig. 1, a and b). In

unilateral clefts of the lip and palate (unilateral alveolar cleft of Sherman) there is usually wider separation of the ends of the nasal ring, more marked flattening of the wing of the nose, with varying degrees of buckling of the alar cartilage and deviation of the nasal septum (Fig. 2). By inspecting the nasal apertures from below it can readily be seen that the longitudinal axis of the orifice has been altered from the vertical to varying degrees of obliquity up to the horizontal (Fig. 3, a and b). Bilateral clefts of the lip and palate (bilateral alveolar cleft) have in addition to the flattening and lowering of the nasal wings, more or less anterosuperior rotation of the premaxilla, with elongation of the vomer and nasal cartilages and shortening of the columella and philtrum, Davis (1). There is usually also some deviation of the septum. It should be remarked that in unilateral clefts of the lip and palate, there is usually lateral displacement of the entire nose, toward the side of the long arm of the alveolar cleft (Fig. 4 a). There is always more or less deformity of the cartilage of the wing of the nose with spreading out of the two halves of the nostril. These halves are attached to the subjacent bony margins by a tense adhesion which resists all displacement and which, with the growth of the face, tends to flatten the nostril and change its long axis to the horizontal (Fig. 4 b), so that the wing of the nose, which is drawn outward, is at the same time somewhat lowered.

THE TIME AND SEQUENCE OF TREATMENT

Closure of the lip with preliminary restoration of the alveolar arch in case the latter is cleft, should be undertaken as early after birth as is consistent with safety. If it is considered unwise to close both lip and alveolus at once, restoration of the alveolar arch should be given preference. In a young infant the shock caused by moulding and securing the alveolar arch is less than it will be later; it is much easier to accomplish, and when effected, it establishes the foundation for a good closure of the lip, with perfect restoration of the nose. Lane (2) says that the best time to operate is "the day of birth or as soon after as possible." Ladd (3) advises "as soon as the birth weight is regained." The best indication of the time for operation is a consistent gain in weight, a good state of nutrition, a normal percentage of hemoglobin and the absence of local infection, (Coe 4). In considering the advisability of early operation in its relation to nasal deformity, Lane (2) says, "In order to treat these cases as efficiently as possible, no time whatever should be lost in restoring to the nose its normal physiology, or in other words, in giving back to it the mechanical factor which alone determines its development, and that of the other structures, which are dependent upon it, to a considerable extent, for their normal form." The earlier the cleft is closed and the nose restored, the less liability there is to respiratory trouble and infections of the sinuses. The constant drying of the nasal and pharyngeal mucosa by the entrance of unmodified air through the widely open cleft, renders facile the implantation and growth of microbial life.

THE SEQUENCE

Inasmuch as the primary restoration of the framework is a fundamental principle of plastic surgery, it seems obvious that to secure a normal lip and nose, any existing deformity of the underlying alveolus should first be corrected. Shearer (5) advocates as the first step "placing the bones in normal position and immobilizing them." Morehead (6) states that the correction of the nasal deformity is solved when the bony arch is corrected, thus making a floor for the nose and bringing it into the median line of the face (Fig. 5 a and b), and he mentions depression of the short segment of the alveolar arch and incomplete reduction of the long segment as two of the commonest causes for the persistence of the low, flat, broad nostril, sometimes seen after operation on the lip. If the lip is closed over an open alveolar arch, the patient will indeed be fortunate if he does not have to be subjected to a secondary operation for the correction of a widened scar; thin, flat lip, or unsightly nostril. Thompson (7) insists that correction of the alveolar deformity must precede every other operation, as it is impossible to repair satisfactorily a lip or nose unless the curve of the alveolar border has been restored and the nasal septum straightened.

TREATMENT

The excellence of the final result depends largely upon primary union of the approximated tissues and this in turn is contingent upon the absence of infection and the highest possible state of resistance in the patient. Owing to the location of the field of operation and the impossibility of expecting cooperation, there is a very lively danger of infection. On the other hand this is somewhat minimized by the great vascularity of the tissues of the face, and can be much lessened by the most careful avoidance of trauma. No sutures should be passed through the skin, the margins of the flaps should not be grasped with tissue forceps or crushed by hemostats, and bleeding should be controlled by gentle pressure. Gauze sponges and wipes should not be rubbed over the field, as blood can be removed with much greater gentleness by means of a suction tube.

The cooperation of a pediatrist to whom the nonsurgical care of the infant may well be left, is vital to complete success. It is important that the child becomes accustomed before operation to the nurse who will have charge of it afterward. This is particularly true with older children. This nurse should not carry the patient to the operating room or aid in restraining him during the administration of the anesthetic, as the child's confidence in her will greatly aid the surgeon in the postoperative care. It is also important that the patient becomes accustomed to the method of feeding which will be used after operation, whether it be by spoon or dropper. Sucking should not be permitted for some time before and after operation, as it tends to increase the deformity of the nostril and widen the scar in the lip. Strapping of the lip with adhesive plaster is of doubtful value in my experience and its small benefit is mitigated by the irritation it causes.

In operating on young children I prefer to have them held in the upright position on the lap of a nurse. This seems to aid in establishing the normal relations, the perspective is better and one is less apt to use too brutal force on the maxilla. Ether anesthesia is most satisfactory in children, while infraorbital blocking has invariably been sufficient in selected adults. In unilateral clefts, the repair of

Fig. 1A

Fig. 1B

Fig. 1A.—E. B., seven months old. Incomplete cleft of lip, flat nostril; longitudinal axis of aperture horizontal.

Fig. 1B.—E. B., three years after operation, repair of nostril satisfactory. Redundancy at free border mars an otherwise good result.

Fig. 4A

Fig. 4B

Fig. 4A.—O. L., four years old. Unilateral cleft of lip and palate; buckling of cartilage and deviation of nose toward long arm of cleft.

Fig. 4B.—O. L., showing attachments of ends of the nasal ring to the underlying bone.

the alveolar border in children younger than three months can be accomplished by moulding the long arm back and in by thumb pressure and securing the ends by some form of suture, as recommended by Thompson (7). After three months it is usually impossible to do this and division of the bone in some manner must be resorted to as a rule. The first step in moulding the jaw is to detach the lip and cheek with the wing of the nose and floor of the nostril, from the underlying bone. It is proper to do this even if repair of the lip is not contemplated at the same time, as in healing, the denuded lip aids greatly in prompt and complete union of the ends of the alveolus.

This mobilization of the soft parts is done through a small incision made quite close to the alveolus as high up in the sulcus as possible so as to leave the mucosa on the posterior surface of the lip undamaged. The soft structures are then pushed away from the bone by a piece of gauze on forceps and bleeding is controlled by pressure. This mobilization of the lips and cheek and wing of the nose is all important, as the final, nice approximation, without the use of tension sutures, depends upon its thoroughness. With the outer surface of the maxilla thus exposed, the bodies of the bones are pushed together by a force exerted through the thumbs on each side of the jaw. Considerable and prolonged effort is sometimes necessary, but it should be continued steadily until the tendency of the alveolus to spring back is overcome. The force must be exerted above the alveolus, otherwise the border may simply be bent inward, leading to bad direction of the teeth later on. As the long arm of the alveolus is forced inward, the pressure is carried forward toward its anterior end and the edges of the cleft are approximated. These ends are then denuded down to the young bone on each side. If they are freshened before the reposition is complete, it may be found that the raw areas do not approximate. In cases where it is impossible to force the alveolar edges together by simple digital pressure, a transverse incision is made with a chisel through the body of the jaw, above the tooth sockets or a vertical incision through the alveolus at the appropriate point for producing a green stick fracture, so as to bring the long arm of the alveolus back into line, thus completing the alveolar curve.

This vertical division of the alveolus is always to be avoided if possible. The bones are then secured in the same manner as stated above but the suture must be carried back farther so as to overlap the point of fracture. In addition it passes from side to side through the nasal fossa above the horizontal palate plates and is tied in front. Wire is used when the edges show a tendency to spring apart after the moulding process is complete and kangaroo tendon when this tendency has been completely overcome. The kangaroo tendon has the obvious advantage that it does not have to be removed, a difficult task sometimes with wire. When the alveolus is the site of a bilateral cleft, the reposition of the premaxillary

bone presents added difficulties, but its complete reduction is of the greatest importance. Under no circumstances should it ever be removed. Its loss causes an irreparable deformity, which only increases with the development of the face (Fig. 6 a and b).

In addition to moulding the jaws to narrow the cleft, the anterosuperior rotation of the premaxilla must be overcome. This is most satisfactorily done by submucous and periosteal section of the pedicle of the premaxilla according to the method of Veau (8). After the pedicle is divided, the premaxilla can be pushed back, in the words of Veau, "as a drawer is pushed in, and not swung on a hinge as a door is turned," as must be done after the removal of sections or division of the vomer and nasal cartilage. By division and reposition of the bone in the manner described, the teeth will later assume a vertical position and not be turned backward, and the cleft can be closed without sacrificing the prominence of the nose. The premaxilla is fixed in position by a suture of silver wire and the soft structures closed immediately if possible, since relaxation has been secured as the first step and the undermining of the soft tissues a second time with the resultant fibrous tissue increase is to be avoided. Closure will help to hold the premaxilla and alveolus in line and add to its blood supply, thus enhancing the probability of solid union of the premaxilla with the lateral arms of the alveolar arch. Both sides of the lip may then be repaired or one side only, leaving the other to a later date. This division of the lip closure into two stages makes it easier to avoid tension on the suture line and prevents flattening of the lip.

FIG. 6A.—C. E., fourteen years old. Unilateral cleft of lip and palate operated upon at three months; premaxillary bone removed; deformity marked and impossible to correct.

FIG. 6B.—C. E. Profile showing approximation of tip of nose and lower lip in patients in whom the premaxilla has been removed.

CORRECTION OF THE NASAL DEFORMITY

The method of closing the lip has as much bearing upon the final correction of the nasal deformity as does the reestablishment of the bony foundation, and it depends upon three factors—1, complete mobilization; 2, conservation of the mucosa, and 3, reconstruction of the orbicularis muscle. In simple clefts and in all others where the defect in the alveolar border can be corrected, it is usually easy to close the lip completely after thorough mobilization of the soft parts, as has been described. In those cases where it is impossible to close the alveolar cleft owing to the age of the patient or the loss of the premaxilla, it may be necessary to make further relaxation incisions transversely under the nose and around the ala. In the operation of Giraldes (9) a flap from the internal border of the cleft lip is turned up to complete the nasal ring and the flap on the external border is used to complete the lip. Berger (10) recommended the separation of the nose from the lip with a lateral relaxation incision into the cheek, and Saurter (11) mobilized the point of the nose by an oblique incision through the cartilaginous septum with liberation of the wing of the nose which was then sutured to the septum at the highest point on the internal border of the cleft. Kuster (12), after mobilizing the nostril by an incision which turns around it, described a small flap from the innermost part of the wing of the nose and sutured it to a denuded area on the highest part of the opposite border. Le Dentu (13) recommended the following procedure as the most perfect for restoration of the

nostril. After mobilization is complete, the posterior and inferior part of the septum at the inner end of the nasal ring is denuded with a sharp knife. A small flap is cut on the uppermost part of the external border of the cleft, and if need be, this can be carried around the wing of the nose to further liberate it. As a rule, however, this is not necessary. The small flap is then turned up and sutured in place against the denuded area on the inner end of the nasal septum.

It is important to avoid excising any portion of the nasal ring at the margins of the cleft, as the cartilage is nearly always shorter than it appears to be and furthermore when its outer end is fitted into the normal position at the base of the columella, close against the premaxilla, the orifice will rarely be found to be too large. Division or resection of wedges of the septum should be avoided if possible.

Conservation of the mucosa of the margins of the cleft is urgently recommended by Lane (2) as an aid in the correction of the nasal deformity. An incision is made through the anterior surface of the margins of the cleft along the junction of the skin and mucosa where it lines the sides of the defect, so as to form a distinct posterior flap. The incisions made in the lip should be as nearly straight as possible and should be carried backward through the full thickness of the lip away from the cleft so as not to remove only a thin strip of the vermilion lining from the anterior edge. When this happens, the sutured lip presents a ridge on each side of the scar which is most unsightly. When this incision has been carried down to the mucosa on the posterior surface of the lip, dividing all muscle fibres, the flaps are turned backward and when the lip is sutured, are turned into the mouth. In this manner any adhesion between the lip and alveolus is avoided assuring mobility and thickness and an appearance of pouting which is so much more desirable than the flatness which only accentuates the prominence of the lower lip. The added thickness due to the conserved mucosa also assures a fullness beneath the nostril which aids in holding the outer end of the nasal ring in position.

In bilateral clefts, the mucosa from the inferior border of the tubercle is turned down to form a deep layer for the lateral arms of the cleft when they are sutured in the median line, and if the lateral incisions are made so as to convert the skin of the tubercle into a triangular, rather than a quadrilateral area, there is less danger of protrusion of the tubercle and flattening of the free edges of the lip after suture (Fig. 7). Veau (4) also has recently insisted upon the preservation of the mucosa as being of the utmost importance in attaining the finest cosmetic results.

When the flaps have been cut and the ends of the nasal ring freshened, after careful observation and measurement of the circumference of the normal nostril, the repair is commenced by uniting the edges of the mucosa on the floor of the nostril inside the anterior aperture so as to narrow it sufficiently, by interrupted sutures of fine horsehair placed so as to evert the margins. The external end of the nasal ring is then carried up and in and secured to the slight hump on the lower innermost point of the nasal septum, thus completing the cartilaginous ring and reforming the slight ridge between the nostril and the upper border of the lip. This is secured from beneath the lip by a suture of fine chromic catgut. A tension suture of waxed silk is passed on a straight intestinal needle from the crease on the outside of the wing of the nose on the cleft side, into the lip below the nasal floor. This grasps the upper fibres of the orbicularis oris and passes across the cleft into its other side traversing the lip at right angles to the cleft beneath the other nostril. It makes its exit at a point in the crease of the sound side exactly opposite its point of entrance. A second suture of the same material is passed one eighth of an inch lower down and parallel to it. The ends on each side are tied over a small piece of rubber tubing, making just enough tension to relieve the strain on the upper part of the lip during crying and to slightly approximate the wings of the nose without narrowing the nasal apertures. This suture approximates the uppermost fibres of the orbicularis muscle and elevates the lip and nostril. The lip is closed with two or three interrupted sutures of waxed black silk passed as on end mattress stitches from the mucosal side, firmly grasping the muscle and not perforating the skin which is closed with a subcuticular suture of waxed silk. This enters at the side of the nose, being tied to the end of the tension suture above and to one of the interrupted sutures which are usually placed in the free vermilion border of the lip. The skin margins are not traumatized in the slightest degree either by needle puncture or the bite of forceps. The conservation of the mucosa gives a fullness to the repaired lip which is always lacking when this tissue is excised. Immediately after operation there is usually an appearance of pouting which disappears in a short time. The perfect alignment of the mucocutaneous junction at the united edges of the cleft is of great importance in the final result. This point must be accurately approximated and held without tension on the skin, so that there will be no scar to break the continuity of the vermilion border (Fig. 8 a and b). Occasionally when the flaps, as cut by Thompson's (7) method, are straightened out, the acuity of the angle makes the farthest points come together with difficulty and if a fine suture is placed in the skin at this point in the hope of close approximation, it almost invariably is tied too tightly and cuts out, leaving a transverse scar in the very place where it is most to be deplored. I have avoided this by marking the points on the mucocutaneous junction with a sharp pointed caliper and then carrying the incision through the mucocutaneous line into the vermilion of the border on one side before turning the knife to cut an angle toward the free border. In this way the two angles are not exactly opposite each other and the tension on the skin of the muco-

Fig. 7.—D. B., five years old. Operated upon elsewhere at three months; marked protrusion of tubercle with a flat lip below it; nose flat and nostrils horizontal; palate completely open; to be operated upon later.

cutaneous line is avoided. This results in nice approximation by means of the subcuticular suture mentioned above and a splendid looking lip. Whitehead varnish is applied within and without to advantage. Incomplete clefts should always be made complete and the formal operation done, in order to thoroughly unite the thin muscle beneath the nostril. However, in those incomplete cases in which the nasal ring is complete and the nostril shapely, it should not be incroached upon (Fig. 9 a and b). Occasionally in older, neglected patients it will be necessary to completely mobilize the entire nose by division of the bony attachments and subsequent manipulation with fixation in the correct position, Blair (15). This is only needed in wide clefts which are complete and a nasal deformity in which plastic procedures on the soft parts are obviously insufficient.

POSTOPERATIVE CARE

The child is kept quiet after reaction by satisfying its hunger and thirst promptly. If possible, the mother is allowed to stay with the infant in the hospital and the breast milk is pumped and fed with a sterile spoon or dropper at regular intervals. In older children, sterile food and water are given according to their custom. If necessary, paregoric and occasionally morphine is given, although it must be remembered that fatalities have ensued from the overadministration of morphine to small children. Examination is avoided as much as possible until three or four days have passed. Then the posterior surface of the lip and the mouth are washed out with sterile water by gentle force from a syringe to remove any food particles which may adhere to the sutures. It does no good to be constantly inspecting the lip, serving only to irritate the child and perhaps increase the danger of infection.

CONCLUSIONS

1.-The correction of the nasal deformity depends on correction of bony framework first.

2. This should be done as soon as is consistent with safety so as to be able to hold the bone without cutting or fracturing it.

3. The premaxilla should always be conserved and replaced by dividing its pedicle rather than excising the vomer or cartilaginous septum.

4. Free mobilization of the cheek, wing and floor of the nose is of prime importance.

5. Conservation of the mucosa on the edges of the cleft is imperative.

6. The floor of the nostril should be narrowed and the axis of the nostril corrected by fixing the outer end of the nasal cartilage up and in against the premaxilla.

7. Avoidance of opposing the angles of the incision at the mucocutaneous border will aid in assuring a smooth continuous vermilion border.

8. Exercise by grimacing and massage of the lip after operation aids in rendering it soft and supple.

The Surgical Treatment of Echinococcosis*

H. W. MILLS, M.R.C.S., L.R.C.P. Lond., F.C.S.
San Bernardino, Cal.

As regards the title of my paper, it might be suggested that the word "surgical" was superfluous, in that there is no treatment of hydatid cysts other than surgical. This, however, would be unwarranted, for when we come to the treatment of hydatid cysts of the lungs, we shall see that there is a large class of the latter in which Dévé has shown that expectant treatment is the correct one, seeing that eighty per cent. of cases so treated result in spontaneous cure by vomica: I refer to the small, deep, parabronchial cysts.[1] And this fact is most important in that any attempt to deal surgically with cysts in this position would be, for obvious reasons, extremely dangerous and difficult. With this solitary exception it is true that (leaving out echinococcosis bavarotyrolienne, which is usually not amenable to any form of treatment) the proper treatment of hydatid cysts is surgical.

One may note in passing that the disease in question is so uncommon in North America that no one individual can have had in this country any clinical experience comparable to that enjoyed by surgeons in some parts of Australia and South America, where many men can count their cases by the hundred, and some by the thousand (Varsi of Rosario, eleven hundred personal operations). Ferguson, however, stated that he had seen at least a hundred cases in Winnipeg between 1882 and 1894 amongst the Icelandic immigrants.

With these preliminary remarks, I will take up seriatim the surgical treatment of hydatid cysts as they occur in the various organs of the body.

LIVER

Seventy-five per cent. of hydatid cysts occur in the liver. I have collected from literature, or through private communications, 170 cases for North America since 1902. The treatment in this situation is always surgical. We will briefly consider the three methods available.

Total extirpation.—As the adventitious capsule itself consists of liver tissue, this practically means resection of that part of the liver containing the cyst. This technic is possible only under very exceptional circumstances, i.e., a more or less pedunculated cyst situated on the anterior hepatic border (Ferrari and Vergos, 1923). One may occasionally

*A paper read in abstract before the Surgical Section of the California State Medical Association at Yosemite, May 19, 1925.

[1]The following authorities concur with Dévé in this opinion: Magnusson; Lugones; Lamas; Pelissier; Verdelet; Zerbino; Pelfort; Bourrat and Cordier; Finochietto; Morquio; Escudero (1922); Lozano; Portu-Pereyra; Peritchitch; Corlette (privately communicated to Dévé); and Barnett. The latest account, and it is a very graphic one, of a spontaneous cure by vomica (in a child age 13) is that by J. Garcia del Diestro (1924).

It is only fair to state that there are a few dissenters: Lenormant; Latteri; Baumgartner and Bardon; Blasco and Gomez; Sergent; Ivanissevich and Arce; and especially Blanc-Fortacin of Madrid, whose article on the subject, in 1922, caused Dévé to return to the charge. In a recent article (February, 1925) Domingo Prat appears as a mild dissenter.

be able to shell out or enucleate a nonparasitic cyst of the liver, but not an hydatid cyst. (*vide* Garré, three cases, cited by Moynihan; *vide* also Buckley.)

The closed method.—The technic here consists of the formolage of Dévé, incision and removal of contents of the cyst, including, of course, the membranes, thorough drying of the cavity left, excision of any redundant cyst wall which may obtain, and tight closure without drainage. In addition, the suture line should be attached to the abdominal wall: this is the "operation of Posadas," known in France as Delbet's operation, in Australia sometimes as Bond's operation, and as a matter of fact, first performed by Knowsley Thornton of England in 1883. Its scope, in the case of clean cysts, has of late years been much extended; it is, in fact, now regarded as the operation of choice, as a perusal of the recent Australian, French, and South American literature will show. Thus, K. D. Fairley of Australia comes out strongly in favor of the closed method in the absence of Barnett's contraindications, which are as follows: rigidity of cyst walls, suppuration, biliary effusion into cyst, rupture of cyst into the surrounding viscera, hemorrhage of cyst wall, and multivesiculation. Vegas and Cranwell give the closure mortality as 2.1 per cent. as against the marsupialization mortality of 4.4 per cent. (D. Prat). Arrizabalaga, 1923, says: "Thornton and Bond invented it; Australian surgeons rapidly abandoned it for simple stabbing; Posadas established it; and Delbet popularized it in Europe."

Cúneo of Entre-Rios, and in fact the majority of South American surgeons favor it, though Deniker wrote, in 1923: "Closure has captured Europe, Argentina is more conservative." In France, Baraduc, Quénu, Routier, Rocher and Masse, and many others have written strongly in its favor. Indeed, there are surgeons (Bond, Kilvington, Russell, Quénu, Brun and Lauriol, 15 cases, 1923; Dupont and Bazy), who go much further, and just as it is more or less fashionable nowadays to omit abdominal drainage in many pus cases, so these enthusiasts apply the closed method to frankly suppurating hydatid cysts. In borderline cases, as in abdominal surgery generally, it is often a very nice point to decide when and when not to drain.

Stewart McKay of Australia drains in hydatid cysts of the liver only when suppuration exists. He is a very strong advocate of the Posadas method. He uses a Finochiettolike apparatus, which makes safe the closing of cysts containing daughter cysts. He emphasizes the necessity of sewing gauze to the skin edges when employing the closed technic.

Zwar of Australia also favors the Posadas method, filling the adventitious capsule with normal saline, a procedure adopted also by Hamilton Russell, but not considered necessary by Morton.

Craig is on the fence in this respect. He says: "Everybody uses the Posadas method, with or without saline."

Kilvington, 1924, disapproves of drainage of hydatid cysts, except those of the lung. He has modified Dévé's formolage to the extent of increasing the strength up to twenty per cent.; in one case he left forty-five c.c. of a ten per cent. solution in a large adventitious capsule with good results. McKay draws the line at ten per cent., and quotes a case in which death was attributed to the leaving of ten per cent. formalin in an hydatid cyst cavity of the thigh.

Incidentally, the closed method of treating suppurating liver cysts of other than hydatid origin has been recently advocated (H. Constantini, Robineau, Delbet and Leveuf).

Meanwhile, the advocates of closure for suppurating hydatid cysts are limited, at present, to a few adventurous spirits. The majority of men of large experience in this particular field are more conservative: Vegas, himself, told me he was among the latter.

With the Posadas operation, if effusion, biliary or otherwise, causes trouble subsequently, it is always a simple matter to tap, and if necessary marsupialize. Meanwhile, the patient has had a chance of a very rapid cure.

Marsupialization and drainage.—This is the accepted treatment for frankly suppurating hydatid cysts, as also for large complicated cysts. It will be remembered that it is sometimes necessary in the case of multiple cysts to attack some of them from the interior of the main cyst. Here, for mechanical reasons, it will be very difficult to make sure that no hydatid débris remains, and consequently marsupialization is the wiser course. The disadvantages of this technic are the slower convalesence of the patient, prolonged suppuration, and the danger of postoperative hernia.

Before concluding my remarks on hydatid cysts of the liver, it is well to mention Finochietto's trocar-aspirator, the use of which, even in Buenos Aires, is still regarded as *sub judice*. The instrument consists of a large trocar (eighteen mm. in diameter) connecting with which is a pumping apparatus. It is designed to rapidly and thoroughly clear out the contents of hydatid cysts, membranes included. The "if" about it is the possibility of leaking fluid around the point of the trocar at the moment that it is plunged into the tense cyst, and this, as a matter of fact, occurred on two occasions on which I saw it used in Buenos Aires. The Argentinian surgeons very carefully wall off the field of operation in these cases, nevertheless the escape of fluid as above mentioned carries with it the possibility of secondary echinococcosis.

The preceding remarks apply only to echinococcosis hydatidosis. For mechanical reasons, usually no treatment, surgical or otherwise, is possible (except theoretically early bloc resection) for the rarer type of echinococcosis bavarotyrolienne. A few such successful excisions have, however, been reported (Bruns, cited by Brumpt: Läwen).

THE LUNG

Incidence ten per cent., second commonest site for hydatid cysts. Eighteen American cases have been reported since Lyon's review. Hydatid cysts of the lung may be divided into: 1. Large cortical cysts; 2. Small central ones. The latter type is not suitable for surgical treatment, as has been pointed out before, and need not here further detain us.

As regards the large superficial cysts, which are far removed from large bloodvessels and from large bronchi, it is almost universally admitted that they should be operated upon as soon as diagnosed.

Cordier, however, is an exception, believing as he does that the question does not depend on the size or site of the cyst, but on the presence or absence of tolerance of the cyst by the surrounding pulmonary parenchyma. However, few instructed persons would permit operation on their own persons for a small central cyst, even if the latter did cause some symptoms, seeing that the chances are four to one that they would recover without it.

The question resolves itself, then, into that of a one stage or a two stage operation, with the consensus of opinion, on the principle of safety first, favoring the latter. The Lamas-Prat-Mondino technic, or some modification thereof, is at the present date the most generally approved one, and I shall here briefly describe it. Costal resection under local anesthesia. Tampon of iodized gauze. Ten days later incision and drainage without anesthesia. The membranes are usually expelled a few days later. Exact x ray localization is essential before each stage of the operation, and the Jockey position is used.

D. Prat, of Montevideo, slightly modifies this procedure. If there are no adhesions (lung can be seen to slip during respiration), he incises the pleura and packs with gauze for twelve days. He remarks that with this technic the lung can be palpated with the finger, and that the entry of a little air does not matter. He removes the membranes, and insists on drainage in all pulmonary cysts, which in his own practice healed in from three to eight weeks without fistulæ. Of fourteen cases without adhesions thus treated, all the patients were cured. In eleven cases in which adhesions were present, there were two deaths. The needle is used as a guide for the knife, the knife for the artery forceps, and the latter must not be removed before the drain is in. He thinks that only six to ten per cent. of cases are cured by spontaneous vomica.

Petit de la Villeon likewise advocates the Lamas operation as being the safest. He provokes adhesions, and ten days later removes the cyst, and drains for a week. He disapproves of Prat's incision, as involving the danger of pneumothorax, and advises investigation in the next intercostal space if, after resection of a rib, the pericostal bed is too thick to permit one to see if the pleura is adherent or no. He characterizes the deliberate production of wide free surgical pneumothorax as a "brilliant but dangerous procedure," and pneumotomy after collarette suture as merely a step towards the later and safer Lamas-Prat-Mondino technic.

Bouzom also advocates the Lamas-Prat-Mondino technic, and reports a case.

It must be admitted, however, that there are many advocates of the one stage operation: thus, Finochietto makes light of pneumothorax, which he says tends to check hemorrhage. He speaks with favor of the extrapleural pneumothorax of Triftia (1895), as also do Baumgartner and Bardon for open cyst (Dévé's comment is: "Is it necessary?"), and uses his trocar-aspirator.

Albertin and Barjon, Guimbellot (229 collected operative cases, marsupialized or closed, with 194 cures), Roux, Quénu, Lavillat, and Acevedo are also one stage men.

Cordier, 1920 (Case III), reported a case of hydatid cysts of the lung which he evacuated and closed. The patient was discharged cured in a month. He warns us to "respect clean vomicæ," and remarks that "it is not the cyst which matters, but the degree of tolerance."

Escudero warns us against operating upon small well tolerated cysts found by chance. He dissents from the theory that vomica is the natural evolution of an hydatid cyst of the lung in man. He quotes Vegas and Cranwell to the effect that in man the parasite has entered, unfortunately for itself, a blind alley. The process should be studied in a natural secondary host, e.g., the pig or the sheep, and not in man. In such animals the normal cycle is not facilitated by the rupture of the vesicle. He regards cure by vomica as a comparatively rare occurrence, and advises operation for badly tolerated cysts, or for hydatid caverns which drain badly. He considers expectancy justifiable, however, in the case of small central cysts, as operation here is difficult and dangerous. As regards technic, he labors the point that both the closed and open methods have their proper fields. He advocates a one stage operation, the Finochietto modification of the Posadas method, for clean uncomplicated cysts, when no bronchial opening is seen. For complicated cysts, or those showing evidence of pericystic infection or open bronchi, he prefers marsupialization, and regards the scope of this procedure as greater than that of the Posadas operation. He insists, however, on the danger of hydatid tuberculosis.

Bourrat says: "If central wait; if peripheral operate. If badly tolerated, operate in the presence of fever and infection. If cyst open and peripheral, operate if suppuration obtains. If central, one may still have to operate, but remember the danger and difficulties!"

Nothwithstanding the differences of opinions above referred to, I think that it is safe to say that the general opinion today is that the Lamas-Prat-Mondino technic for hydatid cysts of the lung, equally with the Posadas operation for hydatid cysts of the liver, hold the field.

There is no difference of opinion at all that, in the case of hydatid cysts of the lung, both formolage and the use of a general anesthetic should be barred. It seems improbable that the preference of a few enthusiasts for the closed method here, as well as in the case of the liver, where its propriety is largely accepted, will spread, in view of the fact that open bronchi, and consequently danger of infection, usually obtains (Finochietto, Stewart McKay, Kilvington).

THE KIDNEY

Incidence 3.30 per cent. (Spurr, 1,302 cases in Buenos Aires hospitals, 1902-1920). Twenty-three American cases have been reported to date.

Here we have generally to choose between partial resection and nephrectomy, bearing in mind that the latter operation is a much less dangerous one in the case of an organ which is almost completely destroyed than when compensatory hypertrophy of the other kidney has not had time to materialize (*vide* case report of Bravo, Spain, 1907). Except when implantation is markedly polar, or the cyst pedunculated (juxtarenal), total removal of the organ will generally be advisable. The dangers of local recurrence and the certainty of dense adhesions resulting

after marsupialization militate against the latter technic, though this procedure may have to be resorted to, as a temporary expedient at any rate, in cases of complicated cysts where the general condition of the patient is poor.

Abadie, 1924, reported two successful cases treated by formolage, partial resection, and closure without drainage.

Aguirre, 1921, reports the case of a girl, aged nine, with a cyst the size of an adult's head, only the inferior pole of the kidney was left. Nephrectomy was successfully performed.

This remark seems sweeping, but a recently reported case by Chevassu (March 7, 1925), lends color to it. A young man, suffering from advanced pulmonary tuberculosis, including pneumothorax, was referred to Chevassu for operation for a large tumor in the right loin of rapid development. He at first declined, but on finding that the functional capacity was good, finally consented to operate, under local anesthesia. Iliolumbar approach, formolage, incision of cyst, and removal of endocyst, which was rich in scolices. Resection of the thin adventitious capsule down to a small collarette, which was then sutured with catgut. Closure of abdominal wall with aluminum bronze wire, with small drain for a few days down to kidney. Excellent recovery. There were no daughter cysts, and the inferior pole of the kidney was intact, the cyst being implanted on the anteroexternal aspect of the kidney.

Soupault, however, in the case of a patient suffering from a suppurating cyst of the left kidney, performed a nephrectomy, while admitting that a considerable amount of healthy kidney remained. He vigorously defends his action.

De Sanctis, 1924, reported a case in which a correct preoperative diagnosis was made by the method of Spurr. The cyst was suppurating and full of daughter cysts. He marsupialized in the first place, but had to do a nephrectomy two months later.

Albarran collected seven cases of transperitoneal nephrectomies, in which five patients died, and three personal cases of lumbar nephrectomies, in all of which the patients recovered.

Houzel's fourteen patients were all treated by nephrectomy and all recovered.

THE BRAIN

Incidence, according to Dévé, 0.6 per cent. in adults, and 4.3 per cent in children. Thus, hydatid cysts of the brain are seven times more frequent in children than in adults. In children they follow the liver and the lungs in point of frequency, whereas in adults more hydatid cysts obtain in the muscles and connective tissue, kidney, spleen, bone, and orbit, than in the brain.

In the recent statistics of Lombard, collected from Vegas and Cranwell, Garcia, Pena, and Thomas, the general incidence is given as three per cent. Five American cases have been reported to date (Granger, Case 7, Lyon; Hyndman, Case 62, Lyon; Mudd, Case 95, Lyon; Miner, Case 224, Lyon; Davis and Balboni, Case 24).

The following is a typical case report: Dimitri and Taubenschlag of Argentina, girl aged twelve. Operation in two stages at intervals of two days. Suture without drainage. Discharged with all symptoms relieved in fifteen days. Well for three years, then readmitted with a clinical picture necessitating further operation. Same technic, main cyst extracted entire, then fifty smaller ones. Gauze drainage. Discharge clear at first, then purulent. Death from meningoencephalitis.

In discussing the surgical treatment here, it is mainly to South America we must look for light. And, as a matter of fact, the immediate surgical results, *quâ* life, have been remarkably good, nearly fifty per cent. of the cases reported in late years having survived operation. The late results, however, are quite a different matter, and are acknowledged to be poor. Dr. Pena showed me, in 1922, a little girl, aged nine, who was quite well eight months after the removal of an hydatid cyst from her brain.

Beauduim advises wide decompression and ablation of cyst, with or without drainage. The mortality in his personal statistics based on thirty-nine cases was seventy-two per cent., of Babonneix, mortality seventy-eight per cent. in eighteen cases, and Vegas seventy-four per cent. in fifteen hydatid cysts of the brain occurring in 952 cases.

Bird of Australia packs the cavity with gauze.

Primary hydatid cysts of the brain are always solitary, metastatic cysts usually multiple (Dévé and Dumont, thirteen cases), the latter inoperable.

The most valuable recent contribution to this subject is that of P. Lombard, of Algiers. He reports one personally successful case, the first operated on in France according to the technic which he now advocates. The patient was an adult male Arab, from whom he removed, at two sittings, an hydatid cyst the size of a large orange from the depth of the left hemisphere. The man recovered, but complete blindness remained. He advises operation in two stages: 1, large decompression, trap door replaced; do not puncture; 2, a few days later, under local anesthesia, tap with a fine needle, and slowly empty pocket; extract membrane en masse, suture exactly, and tap to evacuate air. He states that up to then, 1920, only three cases of two stage operation for cerebral tumor had been published (Foster Kennedy, Ryan, and his personal case), and all recovered. He quotes fifty-three operative cases, in which the immediate mortality was twenty-nine. Death with coma and hyperpyrexia occurred eleven times following rapid decompression, and removal of a large cyst at one sitting. He notes the danger of fatal subsequent pneumocyst; in his own case he had to tap and let out air under pressure. He emphasizes the fact that it is always necessary to extract completely all membranes, and points out that in many of the case reports "cure" should read "progressive improvement," which resulted in thirty-four per cent. of cases in his statistics.

Cases of hydatid cysts of the brain have been reported also by Angland, and Bertrand and Medacovitch of France; by Aievoli, and Sabatini of Italy; by Cardenal and Castella of Spain; by Foresti and Bonaba, de Leon, and Morquio of Uruguay; by Peters of Holland; by Bird, Verco and Poulton, and Ryan of Australia; by Reggiardo, Finochietto, and Rivarola of Argentina; by Ashby, LaPage, Caiger, and Sargent of England; by Fleming and Bury of India.

(*To be concluded*)

Instruments, Apparatus, and Clinical Notes

THE OSCILLOGRAM

Ch. Finck, M.D.

Vittel, France

When a pneumatic cuff connected with a metallic manometer is fixed around a segment of a limb, and when the pressure in this cuff is progressively increased by insufflation of air, one notices that the index needle begins to oscillate, progressively increasing at first, and progressively decreasing between two extreme points, which correspond to the minimum and maximum values of the blood pressure. This fact forms the basis of the technic of the measurement of the blood pressure by the oscillatory method.

By graphically representing the length of oscillations for the various pressures, putting the latter as abscisses and the former as ordinates, a curve is obtained, the shape of which enables one to determine exactly the value of the maximum and the minimum pressures in making a diagnosis of several cardiovascular disorders, and in the case of hypertension frequently to determine the origin of the disorder, especially if one takes at the same time an oscillogram on a peripheral region.

Far too often in researches on blood pressure one forgets to examine the small arteries, the examination generally being concentrated on the large arteries in which elastic tissue predominates, although the variations of blood pressure are mostly due to the variations in calibre of the small arteries with their powerful muscular coats which are likely to contract of themselves. These arterioles react to the most varied influences, physical and chemical as well as nervous.

In order to register the length of oscillations to the various pressures it is necessary to have an apparatus producing oscillations long enough for their amplitude to be estimated with ease. But this condition is in itself a hindrance to the exact reading of pressures which for this reason is not easily noted, and it is necessary to use an apparatus which gives separately the pressures and the amplitude of the oscillations.

DESCRIPTION OF APPARATUS

The scheme given below shows the principle of this apparatus. The entire system (Fig. 1) is composed of a cuff C, which is to be put on the segment of limb where the blood pressure is to be taken; a pump, P, which inflates it; a manometer, M, used for measuring the pressures, and an oscillometer, O, which gives the amplitude of the oscillations to the various pressures. The oscillometer is composed of a strong box, completely closed, in which there is a manometric capsule connected with an index needle, the oscillations of which are visible through a glass lid. The capsule and the box in which it is enclosed are both branched on a tube, T, like all other parts of the apparatus, so that the capsule sustains an equal pressure on its outer and inner surface whatever the pressure may be. In this way the needle remains motionless. A tap, T, enables one to separate the manometric capsule from the box in which it is enclosed, and in this condition, the oscillations of the walls of the artery are transmitted only to the latter, which will reproduce them with the maximum of sensitiveness, the tension of this wall, no matter what the pressure may be, being always nothing until this tap is depressed.

The Pachon oscillometer (Fig. 2) and the plethysmo oscillometer of Spengler and Guillaume (Fig. 3) are the two French apparatuses the most likely to produce the oscillometric curve. If the first gives larger oscillations the latter has the advantage of being easily fitted to any sphygmomanometric apparatus.

The cuff must be long enough to go round the entire segment of limb. The width must be proportioned to the thickness of the limb to be examined; when the cuff is too narrow it gives too high figures for the maximum pressure. It may be stated as a general rule that the width of the cuff must always be equal to the diameter of the limb.

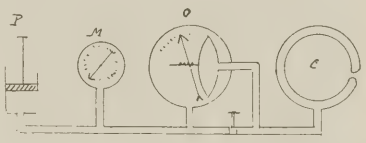

Fig. 1.—Schema of an oscillometer.

Contrary to the general practice by which the limb is lightly compressed at first till the circulation stops on the off side of the cuff, and is then decompressed, it is better to start with progressive compression, as experience has taught us that the sudden isolation of an important area from the general circulation does not happen without some inconvenience for certain patients, such as those suffering from angina pectoris or considerable hypertension.

The cuff having been placed in its appointed position, the pressure is increased, a centimentre of mercury at a time, and the length of the oscillation is noted down for each corresponding pressure. On a sheet of cross lined paper the lengths of oscillations are marked as ordinates and the pressures as abscisses, by joining together the points so marked one obtains an oscillogram. Working along these lines one notices that in a first stage the amplitude of the oscillations increase gradually, the curve being oblique and then suddenly becoming almost vertical.

This change of direction is caused by the production of the first big oscillation, the minimal. After having reached its summit, which corresponds to the largest oscillation, the height of which enables one to estimate the socalled oscillometric index, the curve begins to descend slowly, the oscillations which follow are less and less high as the pressure increases, and then there comes one oscillation, the amplitude of which is so very small in comparison with the preceding oscillation, that the curve drops suddenly.

At this moment, either by palpation or by auscul-

tation, neither pulsation nor any arterial sound may be heard lower than the cuff; the succeeding oscillations are scarcely different one from the other, and the last large oscillation is the maximal. Usually the minimal is seven to eight centimetres, and the maximal eleven to thirteen centimetres of mercury.

The curves in Figs. 4, 5, 6 and 7, were taken on the same patient at intervals of a few minutes, the

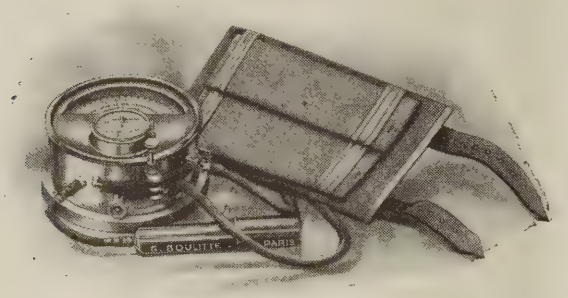

Fig. 2.—Pachon's oscillometer.

first one on the arm, the second on the thigh, the third on the forearm, and the fourth on the leg. Examination shows that the normal oscillogram has the general shape of a steeple with almost symmetrical lateral sides, the slope on the maximal side being slightly more oblique than on the minimal. With the same pressure, oscillations are higher (full line) on the right than on the left (dotted line), so that the curve taken on the right limb covers the curve of the left limb, which is especially the case for the upper limbs. It seems rational enough to ascribe this difference to the anatomical disposition of the arch of the aorta and of the large vessels which start from it as well as to the disposition of the iliac arteries at their origin, the left one reaching lower down than the right.

Comparing the curves of the upper and the lower limbs it will be noted that the height of the maximal oscillation is proportional to the calibre of the examined artery. The highest curve is given by the femoral artery, followed in decreasing order by the curve of the humeral, the curve of the tibials, and the curve of the arteries of the forearm.

The height of the oscillogram of women is, for the same pressure, generally lower than is the case with men. This is evidently due to the fact that adipose tissue is more abundant in women and that it partly deadens the expansion of the arteries. In case of illness, the oscillogram can be modified either in its general shape, or in the relations between the curves of the various limbs.

In hypertensions, these modifications are quite interesting to study, especially if at the same time an oscillogram is taken on a region where arteries have more muscular tissue. The curves will be taken before and after an injection of adrenalin, before and after a carefully watched inhalation of amyl nitrite, or more simply before and after plunging the limbs into a bath at 40° C. at least.

A few examples will give a better idea of the conditions. In the case of plethoric patients who are generally fat, great eaters, great drinkers, with every appearance of robust health, but who have an enlarged liver, an increased blood pressure and viscosity of the blood, the shape of the curve taken on the arm is not much modified. The same holds for the curves taken on the fingers or the legs. The inhalation of amyl nitrite and the injection of adrenalin modify the curve taken on the arm very little, but they respectively increase or decrease the height of the curve on a peripheral area. Capillaries obey the action of vasomotors in normal limits; on the whole, the oscillogram of plethoric patients has a normal shape, with the more or less high elevation of the blood pressure.

The oscillogram of atheromatous patients (Fig. 11) taken on the arm is characterized by a large base and a great height. It has the shape of a roof with a very steep anterior slope (minimal side) and a slightly inclined posterior slope which ends by a sudden drop. Taken on the legs over the ankle it is often reduced to a horizontal line, of very feeble height; neither hot bath nor adrenalin will modify it.

The oscillogram of arteriosclerotic patients (Fig. 10), when taken on the arm, has the shape of a steeple almost symmetrical on its anterior and posterior sides. The minimum tension is generally higher than with atheromatous patients, but the maximum tension is smaller. On the contrary, on peripheric arteries the oscillogram is higher of arteriosclerotic than of atheromatous patients and its shape is easily modified by the use of vasoconstrictors which determine a diminution of height which, however, is less than by the use of vasodilators.

The difference between these two varieties of hypertensive patients is understood when one remembers the characteristics of these two diseases, which so often are taken one for the other.

Atheromatous lesions are mostly to be found on the large and the middlesized arteries (elastic arteries), arteriosclerotic lesions mostly on capillaries (arteriocapillary fibrosis). Atheromatous

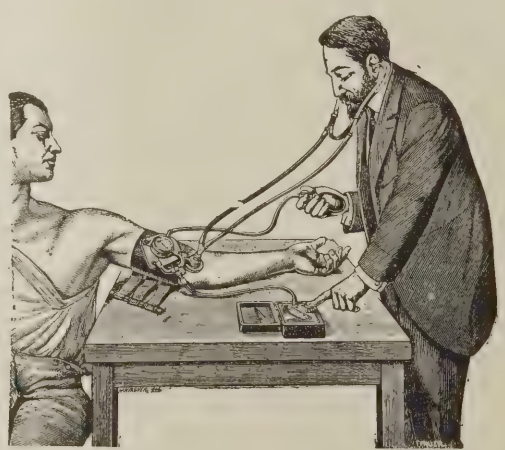

Fig. 3.—Oscillometer (Spencer and Guillaume.)

arteries are hard and infiltrated with cholesterin, the progression of the blood requiring a great effort of the heart, in accordance with the principle that circulation of an equal quantity of liquid at an equal speed in rigid tubes necessitates a stronger impulse than if the tube were elastic. The heart produces its effort by a compensating effort of the ventricle. Patients generally reach the normal term of human

life. In lesions of the abdominal aorta, and of the femoral and tibial arteries, the stricture of the latter is the cause of the lacking of height of the oscillogram taken on the foot. On the contrary, arteriosclerotic patients, whose lesions are mostly capillary, resent no obstacle between the heart and the periphery, so that the cardiac impulse is felt perfectly in the terminal arteries, the cause of a greater height of the oscillogram taken at this level. On the other hand, peripheral resistance is greater than in atheromatous people. Hence, a minimal pressure which is usually very high and only imperfectly counterbalanced by a heart always affected with myocarditis and which is very soon dilated. These patients therefore die young.

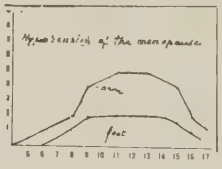

Fig. 8

Fig. 4.—Oscillogram of right and left leg. Fig. 5.—Oscillogram of thigh. Fig. 6.—Oscillogram of forearm. Fig. 7.—Oscillogram of leg. Fig. 8.—Oscillogram of hypertension of the menopause.

Quite by chance one often finds in persons still young high hypertensions which are not revealed by any apparent symptoms. These persons are usually very impressionable. These cases generally occur in businessmen, financiers, and Jews. When taken on a large artery of the arm the oscillogram is marked by a rapid rise of the portion corresponding to the small inframinimal oscillations, by the sudden appearance of a large oscillation, followed by several others still larger, which bring the curve to its maximum height and finally to a descent almost symmetrical with the ascent. The whole curve has the shape of a pointed steeple with very steep lateral sides (Fig. 13). When taken at the periphery the curve presents the general characteristics of the curve taken at the arm but the height of the maximum oscillation is very small. The difference between heights of the central and peripheral curves is even so great that it can lead one to think it is a case of atheroma. A hot bath, an inhalation of amyl nitrite, determine the following modifications: the curve taken at the arm becomes smaller, and the curve taken at the periphery increases in height. Maximum and minimum tensions decrease but return to their first values a few hours later. These hypertensions are the result of a peripheral vascular hypertonicity of an arterial spasm due to a hyperfunctioning of the sympathetic. Some of these patients show signs of hyperepinephritis; others do not. As I already mentioned, these patients stand their condition for a long time and with a minimum of inconvenience. It is much improved by stimulation of the vagus or sedation of the sympathetic.

Fig. 9.—Oscillogram in syphilitic aortitis. Fig. 10.—Oscillogram of arm and leg in arteriosclerosis. Fig. 11.—Oscillogram of arm and leg in atheroma. Fig. 12.—Oscillogram of right arm in aortic regurgitation. Fig. 14.—Oscillogram in aortic aneurysm.

All women suffer at the time of the menopause from a more or less lasting rise in the blood pressure; but in order to study this hypertension it is preferable to examine the women who have had a sudden surgical or radiotherapeutic menopause, for instance, as a result of the cure of a fibroma. The shape of the oscillometric curve at the arm, as well as at the lower limbs, is that of a low dome certainly corresponding to a spasm of the arteries (Fig. 8). The ovarian medication associated with thyroid helps these patients very much. These changes are especially noticeable on an oscillogram taken on peripheral regions.

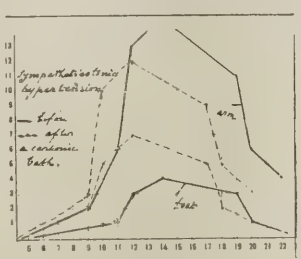

Fig. 13

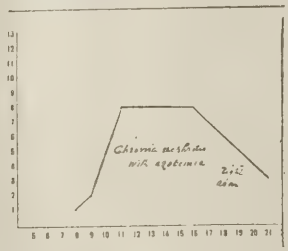

Fig. 15

Fig. 13.—Oscillogram of arm and leg in sympatheticotonic hypertension. Heavy line indicates the condition before a carbonic bath, and the broken line indicates the condition afterwards.

Fig. 15.—Oscillogram in chronic nephritis with azotemia.

Nephritis is always connected with hypertension till the heart begins to falter. The oscillometric curve of patients with retention of nitrogen has a certain resemblance to the curve of atheromatous patients, with the difference that it is lower; it has the shape of a fairly regular trapeze, of a curve of atheroma with the point cut off (Fig. 15). The dis-

appearance of the point of the oscillometric curve and its replacement by an almost horizontal line, the considerable gap between the maximum and minimum tensions are characteristic of nephrosclerosis.

Aortic regurgitation has the characteristic shape of a high dome (Fig. 12), which enables one to make a correct diagnosis at the beginning of the illness when the classical symptoms, including the murmur at the base, are not yet sufficiently strong to be perceived by the ear.

Up to now we have mentioned only curves taken in different but not symmetrical parts of the body. As I showed at the beginning of this article, the curves taken in symmetrical regions do not completely overlie each other, and the curve of the right arm, for instance, will be higher than the curve of the left. This is no longer the case in some pathological conditions where relations are reversed. I pointed out for the first time at the Medical Congress of Brussels in 1921 the inversion of the curves taken on the upper limbs in syphilitic aortitis although the figures of maximum and minimum pressures remained the same on both sides. The fact is so frequent and so particularly related to specific aortitis that one can assert without fail the syphilitic nature of the lesion when it is noticed (Fig. 8).

Aneurysm of the aorta is most easily discovered in this way; besides the fact that the values of the maximum are different on both sides the curve has such an abnormal shape that it is impossible not to think of an aortic ectasia when noticed (Fig. 14).

It is thus possible to help the diagnosis of an illness by the examination of the oscillometric diagram. I have only considered a few cases in this article but it is certain that many diseases have their own oscillometric régime. It is, however, sometimes difficult to discern in complex cases what belongs to each pathogenic element. A little practice will enable one to analyze an oscillogram in the same way one analyzes an electrocardiogram.

HOW TO DRY AND CLEAN HYPODERMIC NEEDLES

Walter M. Brunet, M.D.
Brooklyn, N. Y.

The care of hypodermic needles is, at best, a disagreeable task and oftentimes after a hypodermic or other injection, the needle is laid aside to be cleaned and dried later. Usually when the job of cleaning the needle is reached it is found to be clogged up. Oxidation is the foe of all steel needles

Fig. 1.—Apparatus used by author for drying and cleaning hypodermic needles.

and this destructive power is due to the fact that needles are put away without being properly dried.

The simple inexpensive instrument shown in Fig. 1 is for the purpose of drying and cleaning hypodermic needles.

It consists of a B-D asepto rubber bulb, half ounce capacity, into the neck of which is inserted a male Luer adapter. This adapter fits all Luer needles.

To use this instrument, the adapter is inserted into the hub of the needle and the bulb compressed several times. In this manner, the in and out action of the air through the needle will blow out the moisture and dry it thoroughly.

RECTAL IRRIGATIONS IN THE TREATMENT OF PROSTATITIS

Using the Ear Glass Return Flow Cannula

Ben-Henry Rose, M.D.
New York

Authorities agree that the administration of hot water through rectal irrigations is of decided therapeutic value for the relief and control of acute inflammations of the prostate, prostatic pain, and vesical tenesmus. Hot water may be allowed to flow into the rectum through a single tube attached to an enema bag (such as the Chetwood apparatus); then by disconnecting the tube from the bag, the water

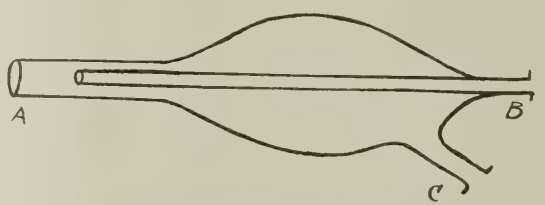

Fig. 1.—Ear glass return flow cannula. A, Tip which is inserted into the anal canal. B, Inflow tip which connects with the tube form the irrigating can. C, Outflow tip which connects with the tube leading into the pail.

is permitted to flow out again,—and so on. This method has the drawback in that it is time consuming.

The combined inflow and outflow rectal tubes may be used, the narrower bored tube being connected with the enema bag, while the wider outflow tube connects with the pail. These tubes are inserted into the anal canal, but the stretching of the anal sphincter muscles by these combined tubes is quite unpleasant and sometimes painful.

I have had occasion recently to prescribe rectal irrigations in a case of acute prostatitis where both the above mentioned methods were used and found to be unsatisfactory. It occurred to me that the ordinary ear glass return flow cannula, so commonly used for aural irrigations, might be used in this case. The upper limb of the proximal end was attached to the tube leading from the enema bag, while the lower limb (the outflow tip) was attached to a tube leading into the pail. The distal end, which measures over an inch in length, was lubricated and inserted into the anal canal. Thus a continuous flow was established, this method giving the maximum amount of comfort and benefit to the patient with the least amount of disturbance.

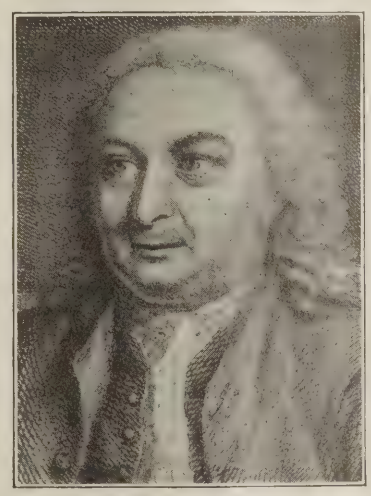
Historical Medicine

Haller and Some Bygone Observations in Pathology

SIR D'ARCY POWER, K.B.E., F.R.C.S., ENG.
London

Albert von Haller, the father of modern physiology, had encyclopedic knowledge. Born in 1708 and dying in 1777, he was a Swiss of the Swiss though many years of his active life were spent as a professor at the Hanoverian University of Göttingen. In early life he had the makings of a first class prig for at the age of four he used to preach to his father's servants; by the time he was nine he had compiled a Chaldee lexicon and at the age of fifteen he had written an epic poem of four thousand verses.

A healthy minded father and a severe tutor fortunately saved him and he grew up to be a level headed, kindly and learned man without any marked eccentricities. In 1757 he published a series of theses which had been read at various universities in Europe by candidates for the degree of Doctor of Medicine.



ALBERT VON HALLER

Many of them are useless, some are curious, as the attempt to explain the polyuria of diabetes by the help of geometry; others are valuable because they show that clinical acumen was as well developed two hundred years ago as it is at present. It is not necessary, therefore, to make any excuse for condensing a few of them for the modern reader. In every European university there was a common form for theses which was followed throughout the eighteenth century.

It began with an invocation to God or with a dedication to the master or professor under whom the candidate had worked. The subject was then stated formally and with such a parade of literary knowledge—Greek from choice, Hebrew occasionally—as would make the greatest impression. One or more cases were then given in detail, the observations having been made at first hand; conclusions were drawn and the whole matter was summed up in a formula capable of being categorically affirmed or denied. The thesis and indeed the whole business was in Latin, not classical of course, but still in Latin, so that it was "in a language not understanded of the people."

A CASE OF PERFORATED DUODENAL ULCER IN 1746

George Hamberger of Jena reported that he had been sent for to see a young woman who had died in a neighboring village on October 6, 1746. He was told that about eight o'clock in the morning she was gathering plums, and had lifted a basket filled with them upon her shoulders. In the evening on reaching home she was seized with violent abdominal pain; on the following day her belly was greatly swollen and she was feverish. She died the same evening but in the presence of some neighbors she had turned to her husband saying, "What have you done to me? Tell me the reason." The doctor was unable to find out from the neighbors whether there had been any other symptom, for instance, increasing fever or vomiting because, as he says very naively, either they were not interested in the illness of a servant or they held their peace lest there should be a magisterial inquiry. At any rate the matter had to be reported; first, because there was swelling of the abdomen far beyond what is usually seen after death; secondly, because of the suddenness of the death, and thirdly, on account of what the woman had said to her husband in the presence of witnesses.

A postmortem examination was ordered and "as soon as the peritoneum was excised flatus rushed violently out of the wound. It was odorless and it was followed by a yellow fluid mixed with small whitish specks. There were about two pounds of it in the abdominal and pelvic cavities. It was easy to see that this material was bilious and mixed with the products of digestion, as often as I raised and depressed the stomach and jejunum, which I did repeatedly, sometimes air and sometimes this stuff escaped. When the liver was slightly retracted I found a small round hole with a blackened edge. It was about the size of a pea and was six lines[1] away from the pylorus. When the duodenum was dissected further the perforation was found to be in the centre of an indurated ring. The centre of the ring formed a round or nearly hemispherical pit covered only with the common membrane (serous coat) without any trace of the other coats, either nervous or muscular, and in the centre of this pit was the perforation. The omentum and the colon near the stomach were inflamed. The stomach contained plum skins with some milk white masses for the patient had taken a great deal of milk and ripe plums. The liver was thickened locally and the uterus was as it ought to be in virgins."

Dr. Hamberger draws the conclusion from these observations that the perforation took place at the time the woman was lifting the heavy basket on to her shoulders. The actual mechanism of perforation being compression of the air which filled the intestines, but because the air was odorless he is in some doubt as to its source. It is interesting that no thought of an operation entered his mind.

The Weed of Insanity

LOUIS J. BRAGMAN, M.D.
Syracuse, N. Y.

Hasheesh, the Arabic for herb, known variously as hashish, bhang, ganja, and charas, is a drug derived from the stalks and leaves of the plant cannabis indica. This plant is a variety of the common hemp, which, according to Cushny (1), possesses pharmacological interest only when cultivated in the warm climates such as Egypt, India, and the southern United States.

From the flowering top of the plant a resin and a volatile oil are obtained. The active principle of the drug is cannabinol, a phenolaldehyde with the formula $OH.C_{20}H_{28}COH$. Therapeutically it is an anodyne, a narcotic, and an antispasmodic in large doses. It is generally prescribed in the form of the extract, one sixth to one half grain, or the tincture, twenty minims. It has some value in the relief of migraine, whooping cough, asthma, paralysis agitans, and sleeplessness.

Cannabis indica has seen service as an intoxicant in Asia and Africa since times unknown, but it was not until the beginning of the nineteenth century that it was introduced into the Western Hemisphere for that purpose. According to estimation, about two hundred million people constantly indulge in it in some form or other, yet this figure is not so astounding as it might seem in view of the fact that the habitual use of small quantities has been shown not to be harmful to Easterners.

There are three methods commonly employed of taking the drug. It is smoked, alone or together with tobacco; it is prepared as an intoxicating drink; or it is mixed with sugar or honey and eaten as a confectionery, a popular medium of ingesting it.

Cannabism is the morbid state produced by the misuse of cannabis indica. The chief consequence is a derangement of the central nervous system, causing a combination of depression and stimulation or mental exaltation similar to that seen with morphine. Its action, however, is far less constant than that of the opiate, for it depends largely on the disposition and intellectual makeup of the consumer.

Soon after taking a large dose a dreamy, semiconscious state supervenes in which judgment is lost and the imagination runs amuck. Definite dreams follow, packed with the vividness of visions and filled with boundless extravagance. Ecstasy, merriment, uncontrollable laughter, selfsatisfaction, and extreme hyperactivity soon abound. Bizarre ideas appear, lacking in continuity. Measurement of time and space is destroyed, a striking feature. Consciousness is not obliterated but a feeling of unreality manifests itself. After the effects wear out a coherent and logical account of the adventures encountered can be related satisfactorily. Convulsive seizures or catalepsy sometimes form the climax of the spree. Continued abuse may finally lead to mania and dementia.

There is no insanity from overindulgence in hasheesh in this country (2) but it is comparatively frequent in Egypt and India. In one asylum alone in Cairo during the year of 1891 there were sixty-four cases of psychosis as the result of inhalation of the weed.

The physical symptoms of cannabism are indigestion, diarrhea, increased appetite, dilatation of the pupils, drooping eyelids, anemia, and general debility. The earliest mental symptom is a marked and increasing timidity. There is sometimes a *folie du doute* or even an agoraphobia. Delirium is usually present and is accompanied by a disturbance of the taste and muscle senses. There is also a complacent feeling of wellbeing together with the sensation of a dreamy, pleasurable existence.

Death from acute poisoning is rare; recovery has taken place after even extremely large doses.

II.

It was pointed out in a previous article (3) that Fitz Hugh Ludlow had undoubtedly transcribed a large fragment of his personal experiences when he wrote: What Shall They Do To Be Saved? (4) an injunction against the misuse of opium. It was likewise mentioned that he had written while still a student at Union College an article on hasheesh which immediately attained a widespread popularity throughout the country.

This article first appeared in *Putnam's Magazine* for September, 1856, as The Hasheesh Eater. It was shortly published by *Harper's* with the appended subtitle: Being Passages From the Life of a Pythagorean. Although absolute evidence is lacking, it does lead to the inference that a later article in *Putnam's* for December, 1856, called The Apocalypse of Hasheesh was incorporated in the book, which unfortunately is not obtainable. This assumption is made in view of the fact that the article deals largely with a theory concerning the relationship between Pythagoras and hasheesh.

It would seem likely then that the same writer who at thirty-three died a martyr to the opium habit, at a much earlier age came into close contact with the mysteries of the noxious weed, cannabis indica.

III.

The Hasheesh Eater is a short sketch in fictional style, purporting to tell of the victim's last association with the drug before he breaks free. During a period of five years in the Orient he had "wandered through the Saharas and oases of hasheesh dreamland"; or putting it otherwise, he relates that "in the palace of alternating pleasure and torture which was for years my abiding place . . . I sometimes reveled with a joy so immense that I may well call it multitudinous; or I ran and shrieked it through its changeful spaces with an agony which the pen of a demon could not describe suitably; surrounded, chased, overclouded by all the phantasms of mythology or the Arabian nights; by every strange, ludicrous, or horrible shape that ever stole into my fancy from books of romance or tales of spectredom."

Under the care of a doctor friend he had finally

succeeded in overcoming his cravings. Leaving the luring East behind he returned home to America, where he met the younger sister of this doctor. He promptly fell in love with her, and even though he freely confessed his past addiction he was accepted by all the family with open arms. His joy was such, he says, that he was "happier than all the hasheesh eaters from Cairo to Stamboul."

One day a package arrived from the doctor who had remained in the Orient. It contained among other mementoes of the Far East a box of hasheesh. The mere sight of it brought a pallor to his cheeks. A member of the family of his betrothed playfully teased him in order to induce him to take some of it that they might witness the action of the strange drug. Spurred on by the harmless intent of the urging he was captured anew by the old temptation and yielded.

Within forty minutes he "began to feel the usual symptoms, the sudden nervous thrill, followed by the whirl and prodigious apparent enlargement of the brain." His head expanded, as he later related, wider and wider, "revolving with inconceivable rapidity in space with every revolution. It filled the room—the house—the city; it became a world peopled with the shapes of men and monsters." He spun away, he remembered, "into its great vortexes, and wandered about its expanses as about a universe."

All perception of time and space was lost, and the distinction "between the realities around him and the phantasmata which sprang in endless succession from his brain disappeared." Through his mind there flashed a series of horrible pictures, a kaleidoscope of fright and terror which he was able to describe later in all its gruesomeness.

He abruptly awoke from his nightmare, which seemingly consumed eons but actually lasted a scant few minutes. He was forevermore finished with the evil "weed of insanity." The lips of his sweetheart, he vowed, would henceforth be the only hasheesh he ever again would taste.

IV.

It may prove of interest to insert for comparison with the foregoing outline of the manner of action of hasheesh a paragraph from a modern novelist touching on the same topic (5):

"My next experiment," he went on, "was made with hasheesh, cannabis indica, which I prepared and took according to the directions of another adept, who had found that the drug produced a kind of demoniac and incessant, hearty, Gargantuan laughter, and the foreshortening of time and space. He could span the distance between London and Paris in a few seconds. Furniture and statues assumed a comic attitude; they seemed to move about and become familiar with him. He was literally aware of what the Rosny have called the *semihumanitie des choses*. I took the drug, as I have said, exactly as he directed, but the effect on me was entirely dissimilar. Immediately I was plunged into immoderate melancholy. The sight of any object immeasurably depressed me. I also noted that my legs and arms had apparently stretched to an abnormal length. I sobbed with despair when I discovered that I could scarcely see to the other end of my laboratory, it seemed so far away. Mounting the stairs to my bedchamber was equivalent to climbing the Himalayas. Although Hadja afterward assured me that I had been under the influence of the drug for only fourteen hours, it was more like fourteen years to me, which I had passed without sleep. At the end of the experiment my nerves revolted under the strain and again I was forced to take to my bed, this time for four days."

In a remarkable volume on *The Mystics, Ascetics, and Saints of India,* by J. Campbell Oman, is found this observation (p. 42):

"It would be an interesting philosophical study to endeavor to trace the influence of these powerful narcotics (charas and bhang) on the minds and bodies of the itinerant monks who habitually use them. We may be sure that these hemp drugs, known since very early times in the East, are not irresponsible for some of its wild dreamings, whilst there is good reason to believe that they have often given the user protection from malarial and other diseases."

In a footnote on the same page the author says:

"The Christian missionary sarcastically remarks, 'A great number of Hindu modern saints live in a state of perpetual intoxication, and call this stupefaction, which arises from smoking intoxicating herbs, *fixing the mind on God.*'"

V.

The thesis is advanced in *The Apocalypse of Hasheesh* that Pythagoras, the Greek philosopher who lived about five hundred years before Christ, received the inspirations for the various tenets of his school while under the influence of hasheesh. His doctrine of metempsychosis, his contention that all things are created and governed according to the laws of numbers, his socalled spheral music, and his choice of symbols, all, the author of the article advocates, bear "the legible stamp of the hasheesh eater."

His own adventures with the drug led him to that conclusion. He had passed through similar experiences while dominated by the fumes and taste of hasheesh, and thus felt capable of vouching for the verisimilitude of the ancient philosopher's system of belief. In his memories of its reaction on him he had found "echoes of a sublime rapture which thrilled and vibrated on the very edge of pain; of Promethean agonies which wrapt the soul like a mantle of fire; of voluptuous delirium which suffused the body with a blush of exquisite languor."

He had learned, too, that "hasheesh is no thing to be played with as a bauble"; for there arrives a time when "the slave of the lamp who comes at the summons of the hasheesh Aladdin will not always cringe in the presence of its master."

The meaning implied in the title is that hasheesh is a potent method of obtaining revelations into metaphysical regions. "The tendency of the hasheesh hallucination is always towards the supernatural or the sublimest forms of the natural." And these "sublime avenues in the spiritual life, at whose gates the soul in its ordinary states is forever blindly groping are opened widely by hasheesh."

It is a veritable open sesame. Problems of the universe, mystical, stupendous, are solved in a flash. The veil is lifted and the obscure made clear.

This then is the apocalypse of hasheesh.

An editorial review in *Harper's Magazine* for 1857, in discussing The Hasheesh Eater shortly after its publication in book form offered the consoling prophecy that "we are in no danger of becoming a nation of hasheesh eaters." The realistic reports that have been submitted above afford nevertheless a fertile source of speculation concerning the peculiar manifestations on the brain of man of that powerful, gripping, and enticing weed of insanity which has entangled not a few victims since its introduction into this country long ago.

History of Medicine in Canada During the Last Century.—Canadians cannot but feel proud when they realize how much has been accomplished in less than a century, writes M. Charlton in the concluding installment of his Outlines of the History of Medicine in Lower Canada (*Annals of Medical History,* September, 1924). Early in the nineteenth century the best medical schools in the world were in Edinburgh. Among the teachers there at that time were Thomas Wakley, James Gregory, Charles Bell, James Syme, John Brown and Robert Christison. When a school of medicine was established in Montreal in 1823, it was singularly appropriate that two young physicians, Dr. John Stephenson and Dr. A. F. Holmes, fresh from Edinburgh, should be chosen as two of the teachers in it. The curriculum at this time counted but four chairs—the practice of medicine, chemistry and materia medica, midwifery, and anatomy and surgery. By 1842, however, each of these subjects constituted an independent department. A few years later, clinical medicine and surgery, the institutes of medicine comprising histology, physiology, general pathology and therapeutics, medical jurisprudence, and botany were added. In 1847 the high price of "board, including lighting, heating and attendance, exclusive of washing," was fixed at $13 a month payable in advance. In 1848 the course of study was extended from three to four years, and each candidate for the degree had to write a thesis on medicine and surgery in Latin, English or French. At this time in Montreal there was a group of noted men at the head of medicine, including F. C. and D. Arnoldi, B. Berthelet, O. T. Bruneau, William Caldwell, G. W. Campbell, James Crawford, A. Hall, William Robertson, Vallée, and Dr. Holmes and Dr. Stephenson.

The Montreal General Hospital had now been in existence ten years. With the addition of a wing added in 1832, its capacity was nineteen wards and one hundred and sixty beds. The staff at this time consisted of Dr. Holmes, Dr. Robertson, Dr. Stephenson, Dr. Bruneau, Dr. Hall, Dr. Campbell, Dr. Crawford, and Dr. Sewell.

In 1829 the medical school ceased its independent existence as Montreal Medical Institution, and became the Medical Faculty of McGill University, the first session of which took place in 1829, and in the next year the medical society, parent of the present one, was organized.

As the year 1832 marked a great advance in medical education in Lower Canada, so it did in Upper Canada. In York (Toronto) medical education was being zealously guarded and advanced by the medical board appointed by the governor. This board inaugurated the movement to build the York Hospital, which in 1824 was described as one of the largest buildings in the Upper Province, but by 1832 it had become too small, so rapidly had York, later Toronto, increased in size. In 1825 George IV granted a charter to the town for the University of Kings College, which included a faculty of medicine. In 1850 the university made it compulsory for students of medicine to have had a degree in arts. In 1795 the provincial parliament of Upper Canada passed an act forbidding the sale of medicine, prescribing for the sick, and the practice of physic, surgery, and midwifery by any one who had not obtained a license. This act was repealed in 1839 and the members of the board were organized into a corporation known as the College of Physicians and Surgeons of Upper Canada, of which the members were to be fellows. All persons then or thereafter authorized to practise physic, surgery or midwifery were to be members of the college, and the college was to license. Women might practise midwifery and those holding a diploma or license from any British university or from any college or faculty of physicians or of surgeons in the United Kingdom, and also all army and navy surgeons. In 1840 the former act came into force again and a new board was formed. In 1853 an act of the Legislature swept away the medical school of the university, which, whatever its faults, had in it the elements of ultimate success, and left the profession and the public at the mercy of irresponsible schools without foundations and dependent on private enterprise. "There could be no doubt that the abolition of the Faculty of Medicine of the University of Toronto retarded seriously the growth of the profession in this country."

In 1850 the Upper Canada School of Medicine was established in Toronto, which in its first session became the Medical Faculty of Trinity College, and after three years passed out of existence because the professors resigned on account of certain vexatious religious tests to which they were submitted by the corporation. The Faculty of Medicine of Victoria College was next established in Toronto but ceased in 1869. Then another school was organized in form and name a continuation of the old Toronto School of Medicine, and began operation in cooperation with the University of Toronto in 1857. In 1870-71 a new medical faculty was organized in Trinity University. The first medical journal published in Canada was the *Upper Canada Journal of Medical, Surgical and Physical Science,* 1851-52. Later came the *Montreal Medical Gazette,* the *British American Medical and Physical Journal,* the *Canada Medical Journal and Monthly Record of Medical and Surgical Science,* the *Canada Medical and Surgical Journal,* the *Maritime Medical News,* and the *Montreal Medical Journal* which became in 1910 the *Canadian Medical Association Journal.*

In 1720 the presence of plague epidemics in Europe brought up the question of quarantine of Canadian ports, and the writer gives a detailed history of the whole problem in that country.

In 1843 the McGill Medical Faculty founded the University Lying-In Hospital; there was another at the Hôpital de St. Pelagie. The first dispensary in the city was opened also in 1843, and in the same year the Legislature passed the Anatomy Bill, and a new bill for regulating the study and practice of medicine. An important item was the penalty clause protecting the licensed practitioner from quacks. In 1848 Dr. Douglass, of Quebec, manufactured chloroform and it was successfully used in one of the hospitals in that year. In 1851 a new medical school was started under the name of the St. Lawrence School of Medicine of Montreal, but it lived for a short time. A new hospital was also started called St. Patrick's Hospital, which was absorbed after an existence of twelve years by the Hôtel Dieu.

In writing of the men responsible for this progress in medical education in Canada during the last century, the writer says: "From the first quarter of the nineteenth century when laws regulating the practice of medicine began to be made, steady progress has been made towards the ideal. Canada has provided well equipped men, who in their character, training and disposition were worthy of the great trust reposed in them in the bettering of medical education. They gave a wholesouled devotion to their work. Their enthusiasm and devotion were in turn communicated to their students and those students, who in turn were to become teachers, seemed to be embued with the same love of their work and followed in the footsteps of their masters."

The Skin of Our Ancestors.—That from the most remote times our ancestors have had to suffer from various dermatoses, is a fact almost assured, although it cannot be demonstrated. This Prof. Paul Raymond tells us (*Æsculape,* April, 1925) in an article covering the period from the reindeer age to the time of the Roman republic. This fact seems to be well substantiated from pathological bone fragments from prehistoric graves. Among these bones found in graves of the stone age, the bronze and the iron age, may be seen evidences of morbid states accompanying ordinary cutaneous diseases such as tuberculosis, for example, or syphilis. Although we have no definite proofs, we have at least numerous indications of the care of the skin taken by our forefathers of the reindeer age and the periods following. "For example, I once found," he says, "in a grotto a stone plate with a central hollow, a veritable cup of colors bearing still traces of a pomade of iron oxide. Beside it was pestle still covered with clay and a considerable quantity of reindeer bone, crushed for extracting the marrow." In other caves have been often found, beside similar animal bones, fragments of red or yellow ochre, deposits of manganese in fossil shells, leaving no doubt of their use as skin ointments for esthetic purposes, or of a therapeutic which we must guess at rather than prove.

Then appear at the end of stone age and especially in the copper and then the bronze age, metal instruments, pure copper or bronze, whose use is evident, proving that care of the skin, painting of the body, and tatooing were common customs in prehistoric times. Of their use until they became abuses, then diseases, is only a step, and we know in our times all the dermatoses that must have been the results of paint and cosmetics with which the ancients took pains to ornament their countenances "to repair the irreparable outrage of the years." [The quotations are the author's.] To the iron age belong the silver or bronze instruments found in the tombs of the Mycenean epoch similar to those depilatories which later the Romans used so much. At this epoch preceding the Roman conquests the use of pomades and paint already existed, for Pliny and Cæsar tell us that the Bretons colored themselves with pastels, the Picts owed even their name to the paint which they used similarly. From the Roman epoch we recognize the socalled tear vases, which were nothing more than vessels for unguents, the Romans including under this term many more medicaments than can rightly be called ointments. Ovid, Tibullus, Propertius, Juvenal and especially the naughty tongue of Martial discourse upon the multicolored paints which the beauties of Rome used for concealing their wrinkles.

The hair was, we know, among the Romans of both sexes the object of special care, and, if with us baldness is sometimes respected, it was not at all the case in Rome. It was concealed by every possible means and it was said that it was only to hide his bald head that Cæsar always wore a crown of leaves in public. Tibullus tells us that his contemporaries knew how to turn raven black a head as white as snow by means of nut shells. Ovid speaks of the juices of German plants, and Martial adds: *Tum subito corvus, quae modo cycnus erat.*

Medical Details in the History of Apollonius of Tyre.—Among the romances of the Greek Sophists composed between the first and fifth centuries of our era, beside the Daphne and Chloe of Longus appears the History of Apollonius of Tyre, almost forgotten today, but which enjoyed in the Middle Ages a great popularity. In this romance M. Bugiel in a paper recently read before the Société Française d'Histoire de la Médecine (*Æsculape,* May, 1925) has pointed out some interesting details of medical history. He has made a long study of them, and, by comparing them with many passages from the ancient Greek physicians, shows us that the author, Apollonius of Tyre, must have been well acquainted with the medical science of his day.

The promenade on the seashore of the physician Cheremon with his pupils proves that the doctor was always accompanied by students when he made his visits to patients. Noteworthy also is the passage where one of the pupils of Chemeron examines the corpse which has been cast up by the sea. This medical examination proves to us that physicians of the third century had at their disposal as means of diagnosis palpation, examination of the pulse, investigation of respiration and temperature of the body. They followed the directions of Hippocrates: "Note from the first the resemblances and dissimilarities with the state of health, the most important for their results, the easiest to recognize being those which supply all the means for observation; examine all you can see, feel, hear, all that can be perceived through sight, touch, hearing, smell, taste, and the use of intelligence."

HEALTH EDUCATION IN HIGH SCHOOLS

Dr. Franklin W. Barrows, of the New York State Department of Education, makes a stirring plea for the introduction of health education courses into all high schools, in the *Nation's Health* for November, 1924. His idea is to base these courses on what the young men and young women of today really want the high school to teach them in continuation of their elementary courses in hygiene. Dr. Barrows believes that they want "information on personal hygiene that they can make use of; more knowledge of the human organs and functions; more human biology; hygiene of the various organs."

Dr. Barrows bases his belief partly on the fact that the question was answered by a group of high school students themselves who were asked what they wanted in this line. One fifth of the number asked for heredity; sex problems and sex hygiene came second in choice. His plan for a course suitable for these high school boys and girls would include, first a general review of hygiene, exalting it as "the natural fruit of a genuine acquaintance with the body and its workings." Two topics should receive special emphasis because they are not fully treated in the grades, namely, nutrition and reproduction, with its cognate endocrinology. Next group hygiene—family, community, state, nation, should be emphasized, leading up to the hygiene of international relationships. Then courses in safety first, home nursing, etc., may be given, as simply as possible so as not to overwhelm the student with an overweening sense of responsibility toward the welfare of the universe. Industrial health may be touched upon in some of its phases, especially that of vocational guidance. The last high school year is the time to study mental hygiene, in Dr. Barrow's opinion, and its relation to individual efficiency, fatigue, the use of leisure, and the prevention of nervous and mental disturbances. He makes a special plea for the proper teaching of sex hygiene. "Our morning papers," he writes, "do not scruple to supply the breakfast table with front page details of vulgar and questionable 'romances' unearthed in our criminal courts and enlivened by columns of phosphorescent rot on love nests and love babies, while of sane and serious material on the source of this lurid stuff the editor and all his talented assistants give us not a single word. Too many of our young women, some of them scarcely out of school, bring forth their first born in ignorance, dread, and apprehension, knowing little or nothing of the functions of motherhood, its dangers or its compensations. The home, the church and the school in this intelligent age do less to prepare them for the responsibilities of propagation than the stockbreeder is doing for his sows and his mares." He adds that such a course should include in part reproduction, development, from birth through adolescence, parenthood and child care, artificial selection, heredity, Mendel's law, feeblemindedness, race poisons, social health and disease (without emphasis on disease); and the sanctity of the family. He states that he is sure that there is no high school in our country that cannot find available some man to teach such things to the boys, and some woman to do the same for the girls.

MALARIA IN COLD CLIMATES

It seems that cold is not a barrier to the pernicious activities of the malaria bearing mosquito, as malaria is extremely prevalent at the present time in the cold regions of Russia. During the war in 1915 certain parts of Mesopotamia, in extremely cold weather, were infested with malaria. On account of the cold weather, no one suspected the presence of malaria, and it was not until the arrival of a medical man, who had had wide experience in tropical diseases, that a correct diagnosis was made. It has been suggested that if in Mesopotamia, as in East Africa, malaria experts had been sent up to report at the beginning of the campaign instead of when it was nearly over, thousands of lives would have been saved. It has been further stated that frequently in malaria districts in cold weather, when no signs of breeding remained, infected female anopheles, not hibernating but living in a state of biting activity, may be found. But it has been declared recently by a medical man in Russia that there mosquitoes breed in the water butts in the houses during the winter.

If this is really true it renders the problem of eradication a difficult one indeed. If, as in other regions, breeding ceases in the cold weather and the males die out, the curtailment of the spread of the disease is by no means impossible, in spite of the fear that all the usual mosquito sanitation methods during the summer may be out of the question among so ignorant a population. Compulsory house fumigation and disinfection during the winter, together with individual quinine treatment, might have beneficial effects, if it were not for the hopeless lack of education said to exist in South Russia.

If the malaria mosquito can transmit malaria in cold weather then malaria is an even more prevalent and deadly disease than it is supposed to be. There is little doubt that malaria is the most injurious disease to health if not the most deadly known. During the war it took greater toll of the combatants than any other disease. In Macedonia it was endemic and killed and incapacitated thousands. It was rife in Mesopotamia and more or less prevalent in other areas in the Near East in which fighting was carried out.

Why should not a world wide campaign be waged against malaria, at any rate in populated districts and where such a campaign is likely to be successful? It is a disease, the abolition or abatement of which should appeal especially to Americans, as there are many regions in this country in which it is endemic.

TONSIL FETISHISM

Many convalescent homes devoted to the care of children with rheumatic heart disease refuse admission to all candidates who are still in possession of their tonsils. As a consequence, the physicians of many cardiac clinics (in New York city at least) are compelled to have tonsillectomies performed on all patients who need convalescent care. The evidence that removal of the tonsils will prevent recurrences of rheumatic infection is not convincing and the operation is not so innocuous as many would have us suppose. Many children require months to recover from the general deleterious effects of a tonsillectomy. Crowe (*Bulletin Johns Hopkins Hospital,* 28:1; 1917) and his coworkers, in a carefuly study of patients whose tonsils had been removed, reported that of twenty-five patients who had had rheumatic fever, recurrences took place in four after tonsillectomy, and that of twenty-four patients who had had chorea, the symptoms returned in eleven. These recurrences occurred in from three weeks to three years after the operation. On the average the patients were under observation only two years. More recently St. Lawrence has reported a more intensive study of eighty-five children who were observed during an average period of three and one half years after the operation was performed. Thirty-one of these children, or 36.5 per cent., showed recurrences in this period. Recurrences were more frequent in those with chorea than with the other rheumatic manifestations. St. Lawrence stresses the fact that many patients who had had constant and frequently recurring manifestations for a period of years before the operation remained free of symptoms thereafter. On the other hand, he reports cases in which there had been no history of tonsillitis or any rheumatic manifestations before the tonsillectomy was performed and yet, which, years after complete tonsillectomy, showed acute rheumatic fever or some other allied manifestation. Many patients develop acute pharyngitis instead of tonsillitis after their tonsils have been removed. Hunt and Osman (*Guy's Hospital Report,* 73; 383; 1923) who have studied the after histories of 114 patients who had been patients in Guy's Hospital with acute rheumatic fever. found a greater percentage of relapses of manifest rheumatic fever in the patients whose tonsils had been enucleated. Of 166 patients whose tonsils had been completely removed, thirty-five, or fifty-three per cent., had definite recurrences, while of seventy-eight nonoperated patients, thirty-three, or forty-two per cent., had renewed rheumatic attacks. Their figures seem to show that recurrences are more frequent in patients with rheumatic heart lesions. This suggests the possibility that the virus may remain latent in the heart and from there initiate a new systemic infection. Ingerman and Wilson (*Journal A. M. A.,* 82; 759; 1924) were unable to establish the fact that rheumatic recurrences were lessened as a result of tonsillectomy.

In view of the doubtful value of tonsillectomy in the prevention of rheumatic reinfection, the convalescent homes in question are undertaking a grave responsibility in making this operation a prerequisite for admission. Physicians who yield to their ruling, without determining for themselves whether or not there is a strict indication for the removal of the tonsils of the applicant, are not serving the best interests of their patients. In this, as in all medical problems, generalized and blanket rules cannot, with justice to the patient and with adherence to a spirit of strict scientific inquiry, be substituted for a careful and conscientious individualization.

DISEASES OF ADULT LIFE

Arteriosclerosis is the most prominent disease or condition which tends to shorten the span of life. It is a symptom rather than a disease, although authorities do not agree as to its precise etiological factors. Some hold that arterial thickening is frequently of syphilitic origin. Sir Thomas Horder, who writes on the subject in the *Practitioner,* July, 1925, is utterly opposed to this theory, and states that many, if not most of the actual cases that come under observation are obscure in their pathogenesis. The most popular current view is that they are toxic. The toxemia is attributed to absorption from the bowel of certain products of microbic activity or to metabolic defects. Metchnikoff, the first great apostle of the doctrine of autointoxication, said in

Annales de l'Institut Pasteur, 1910, that the digestive tube is constantly elaborating poisons of microbic origin which are capable in time of setting up physiological arteriosclerosis. Bishop, in this journal for September 9, 1911, said that the vast majority of cases of arteriosclerosis as they occur in adult life are due to the indirect influence of intestinal putrefaction upon the blood vessels and nervous tissue. Horder points out that two possible factors are prone to be overlooked, inheritance and nerve strain, but admits that the causative factors and the indications given for treatment may be considered under three heads, nerve strain, microbic infection, and biochemical errors. It is pointed out also that the term autointoxication has changed its meaning. Originally used to connote toxic states arising as the result of biochemical defects, gout, acidosis and so on, it has come to mean a condition of poisoning due to the absorption of microbic toxins. The author does not commit himself to the theory that intestinal toxemia is the root of the trouble, although he allows that the colon may be the reservoir of poisonous substances, hence may come the autointoxication. He believes that the nerve strain plays a prominent part in the causation of arteriosclerosis, indeed it may be gathered from the tenor of the article that this appears to be his pet view. However, he thoroughly subscribes to the efficiency of efficient drainage, presumably by way of the gastrointestinal and urinary tracts. As for drugs, in his experience, iodine seems to be the most helpful. The keynote of treatment is moderation in all things, the avoidance of nerve strain, and the securing of plenty of rest.

TYPHOID FEVER

In accordance with instructions received from the Commissioner of Health of New York City, a study was made of the features of public health interest connected with the recent typhoid fever outbreak in the city. *Monthly Bulletins* Nos. 2-4 of the Health Department are devoted principally to this subject, which is reported by Dr. Louis I. Harris, director of the Bureau of Preventable Diseases of the Department of Health of New York City.

The report states that the outbreak came as a sharp reminder that the gains we have made in the protection of public health against typhoid fever and other diseases are insecurely held, and depend upon a vigilant, unremitting and firm control of the various safeguards which we have learned to erect against communicable diseases.

One peculiarity of the recent outbreak was that in not a few of the cases the common accepted diagnostic signs and evidence of typhoid fever were lacking until the disease had nearly or entirely run its course. "This observation argues powerfully for the need of instituting typhoid treatment and precautions in all obscure cases marked by a continuous febrile course, as a measure of protection to the patients and the public. It shows the wisdom of repeatedly submitting specimens for culture, Widal tests, differential counts, and stool examinations, in all masked and atypical cases." "If this outbreak had been due to a polluted water or milk supply, it would inevitably have affected many times the number of children recorded."

Of the 914 cases recorded in the outbreak, 116 residents and fifty-nine nonresidents who were included gave a history of having been out of town during the period immediately antedating incubation. The majority of these had eaten oysters while out of town, while others gave a varied history of their activities and presumable exposures. The close social, commercial and transportation ties that bind New York city and a host of other cities, near and distant, make for reciprocation in the transmission, not only of typhoid fever, but also of other communicable diseases, so that we are constantly reminded that there is a community of interests in health protection among all cities that makes the health condition of any important city the concern of all others.

One death occurred among twenty-eight immunized cases, a case fatality rate of only three and six tenths per cent. There were forty-two patients who received one or more injections after atypical symptoms of the disease had made their appearance. In such individuals the injections were obviously impotent for preventive purposes for five ended fatally. "If the new and generally unknown method of administering a vaccine containing killed typhoid bacilli by mouth, following a small dose of oxgall, is found to be as effective as it is said to be by Besredka and by others, it shoud go far to overcome the general disinclination of people to submit to vaccination by hypodermic injections, and prove a valuable measure of public health to those who go out of town."

The 506 cases giving a definite oyster history represent approximately seventy-eight per cent. of the excess number of typhoid cases of the recent outbreak. Making allowance for minor outbreaks due to carriers and lesser causes, it seems that there is a strong likelihood that infected oysters may have played a larger part in past years than has been suspected, and that this may have escaped detection because the cases caused by them were lost in the general shuffle during the summer and fall seasons, and because probably the sources of pollution of oyster beds have increased slowly until they reached a point where trouble was caused on a wholesale

scale. The fact that the majority of cases of typhoid fever in the period under discussion were confined to the well to do argues for oyster infection as the principal cause, since these people, needless to say, are more given to dining out and to the consumption of rich foods than the poor.

The remainder of the report (the third section published in the June issue of the *Bulletin*) is devoted chiefly to the citation of further indications that the source of the infection was polluted oyster beds, not those of West Sayville alone, to which the outbreak was attributed, but to many others. Ways in which oyster beds receive contamination are described, especially those near New York, and a tentative program is suggested to remedy the situation.

The report states also that a relatively large number of the cases of the recent outbreak were apparently due to bathing in polluted water, testifying to the inevitable increase of pollution due to the rapid growth of many cities and towns adding their share to the waste and sewage discharged into the various waters that were apparently responsible for these infections. Another point mentioned is that the number of typhoid carriers is, naturally, increased with an increase in the number of cases. A few months ago there were 160 carriers under supervision; there were at the time of the making of the report twenty-six more temporary carriers, and twenty-six more convalescent carriers.

SIR WILLIAM OSLER

Although the late Sir William Osler was born and received his medical education in Canada and lived for many years in England, where he died, he passed the best part of his life and made his reputation in this country. As a matter of fact, the medical profession here regard Osler as an American physician. It is fitting therefore that his life should have been written by a distinguished professor of Johns Hopkins Medical School, where Osler was also a prominent figure. Harvey Cushing, the author of the biography just published by the Oxford University Press, was a colleague of Osler and knew him intimately from the medical as well as the social and domestic viewpoints.

William Osler was born in a Canadian parsonage near Toronto, by descent a Cornishman and a very Celt of the Celts in temperament, but strictly disciplined. First of all, Osler was a teacher, and it is largely due to his efforts that medical education in this country has advanced to its present high standard. He was well endowed by nature and by training for bringing order out of what might almost be termed chaos, as he possessed in the highest degree the iron hand in the silken glove and wonderful gifts of intuition. He had both personality and charm, an alert brain, a wonderful memory, and untiring industry. However, it was his love of humanity, expressed with Celtic lack of reserve, which more than scholarship, diagnostic ability, or other attributes made him the power he was. The heart in Osler spoke more powerfully than the brain. They who met him felt that he was genuine; he was courteous always and made personal friends of those who worked with him.

Osler excelled in placing his views on paper and his writings were real literature. His textbook of medicine was a stupendous success and in the fields of pure literature he wrote with the wit, buoyancy, almost abandon of the Celt, albeit controlled by knowledge. As a literary medical writer Osler may be compared with Sir Clifford Allbutt, another great physician of commanding knowledge and personality combined with exceptional powers of expression. Osler was a pioneer of preventive medicine, perhaps it may be said creative medicine, and somewhat of a drug nihilist. He was a master physician and a reformer, whose clinical knowledge told him that prevention was better than cure, an axiom which he taught and practised.

While Osler's career is his monument, the book by Harvey Cushing will help to keep his memory green. Without a biographer nothing is remembered of many great men.

HEALTH CONDITIONS FOR WORKERS IN RUSSIA

The British Labor Party recently sent to Russia to study conditions there for workers four women, three of whom are organizers in various trades and the fourth a worker in a textile union. A preliminary report of this visit has recently been issued which gives some interesting data on what the present Russian Government has been able already to accomplish along lines of improving working conditions.

Women are encouraged to enter as far as possible all classes of work; they are encouraged to become skilled in every branch of industry, and they receive equal pay for equal work. The entry of women into the trades is facilitated by the fact that most of the factories have day nurseries and even kindergartens where the children may be left with safety and profit. In most cases the children left thus are cared for and fed free of charge.

Every woman factory worker gets two months' leave of absence before and after the birth of a child, with full pay; in addition an allowance is given, either in money or kind—usually the latter—to provide for the baby's clothes and other necessaries; and free medical attention is supplied.

Women clerks and brain workers usually get six weeks before and after. Work canteens in the factories provide meals for the employees and their children, with a view to relieving women from some of the drudgery of home keeping, and there are also community and cooperative dining rooms. Most factories have a club for entertaining the workers in the evening, and, in order that the mothers may participate and attend educational and trade union meetings, here again special accommodations with trained attendants are provided for the children.

A minimum of two weeks' vacation on pay is statutory, and there are a number of religious and national holidays. An extra two weeks' vacation is granted to workers in unhealthy or dangerous trades. One of the most interesting and beneficial features of the present system is the large number of rest homes where the people may spend their vacations, all free of charge. These homes are for the most part the mansions and palaces of former Russian princes, nobles and rich merchants. All traveling expenses are paid for the workers, and they receive wages in full during their rest periods. Organization is being perfected of a system of sanitoriums and health institutes for the care and treatment of various diseases, such as tuberculosis, nervous diseases, and heart trouble. In many parts of the country improved workmen's homes and peasants' dwellings are being built, with all the modern sanitary conveniences. This means of course a complete revolution in the life of the people. Garden cities planned after those in the United States and some of the European countries are being constructed out of the profits of the various industries.

In outlining this report the *Manchester Guardian Weekly* adds: "An enormous amount of work still awaits the Soviet authorities, not only in the restoration and improvement of industry and agriculture, but also in the sphere of housing, education, public health, and particularly in the construction of a proper draining system. Nevertheless, what has already been done in most of these directions proves that, even unaided, Soviet Russia is making good."

TROPICAL HEALTH EXHIBITS AT WEMBLEY

Among the most interesting exhibits at the British Empire Exhibition are those of the Tropical Disease Section. Two scenes, the first entitled ignorance and the second knowledge, stand side by side in this section. The first shows an English explorer, wasted almost to a skeleton by repeated attacks of malaria. Attended by two faithful servants, he lies at the point of death just outside a miserable native hut in an open space in the tropical forest. Across the foreground a sluggish stream crawls through the undergrowth, which, together with the great trees, surrounds the sick man and his servants with a rank profusion of vegetation, brightened with a flock of brilliant tropical butterflies. The stream is the breeding place of countless hordes of mosquitoes.

The second setting shows us the same spot twenty-five years later, when "knowledge" and intelligent human effort have transformed the whole place, which has now become a centre of health and prosperity. The forest has been cleared away, the stream confined between grassy, sloping banks and cleared of all vegetation. A film of oil is continuously and automatically spread over its surface as a protection against any mosquito larvæ. The primitive hut has been replaced with well built native cabins, and a bungalow for the white man equipped with screens and mosquito proof beds stands by. The settler has his wife with him, and, apparently they are now "living happily ever after." These two exhibits have continuously drawn immense crowds.

Throughout the whole health exhibition prevention is emphasized in the account of each disease. An original device presents statistics graphically, and so simply that no one could fail to grasp their significance. Sleeping sickness, malaria, blackwater and yellow fevers are illustrated by photographs and models. The plague exhibit contains a collection of interesting historical pictures showing ancient superstitions connected with the disease, and specimens of some of the leaden crosses which it was the custom to bury with plague corpses. Dysentery, hookworm, and cholera are described, as well as the less known diseases, such as elephantiasis, bilharziasis, beriberi, and kalaazar. Some of the representations of leprosy are almost too realistic for the layman in the horrors they depict, but assurance is given that the disease is not now considered as inevitably hopeless. One of the most interesting exhibits is that showing methods of protection against sunstroke, and the terrible heat of the tropics.

Around the whole exhibit of the tropical disease section runs an attractive frieze in black and gold with quotations from famous experts in tropical diseases and illustrated with insect and animal designs. Chaucer's statement, probably forgotten by most of us, even the doctors, is included that "Men wel ofte ben slayn with bytinge of smale flyes."

News Items.

Harvey Society Lecture.—The first lecture of the Harvey Society for the season was given Saturday evening, October 3rd, at the New York Academy of Medicine, by Dr. F. R. Nager, professor of otology of the University of Zurich. His subject was New Problems in Otology.

New York Academy of Medicine.—The first stated meeting of the New York Academy was held October first, the program being presented by the Albany Medical College. The first meetings of the sections on surgery and on dermatology and syphilis were held during the week. The sections on pediatrics and on neurology and psychiatry will be held October 10th and October 13th, respectively.

Prize Awards.—The Leonard prize of the Röntgen Ray Society, in amount one thousand dollars, and the gold medal of the American Radiological Society, have each been awarded to Dr. Everts Ambrose Graham, Dr. Glover M. Gopher, and Dr. Warren H. Cole, of St. Louis, jointly for investigations in the diagnosis of gallbladder disease.

West Virginia in Registration Area.—West Virginia has been admitted to the birth and death registration areas for 1925.

Plague Quarantine Lifted.—The ports of Oakland and San Pedro, California, and New Orleans have been declared free from plague by the Surgeon General of the Public Health Service.

American Stomatological Association.—This organization has been admitted to membership in the International Stomatological Association. Dr. Alfred J. Asgis, of New York, has been appointed adjunct secretary general.

Chicago Medical Society.—The annual dinner of the Chicago Medical Society will be held October 14th, at which time new officers will be installed. Dr. William Allen Pusey will be toastmaster.

Physiotherapeutic Convention.—The fourth annual Physiotherapeutic Convention, held under the auspices of the educational department of H. G. Fischer and Company, will take place in Chicago, October 12th to 16th.

Cost of Psychiatric Treatment.—A recent report indicates the per capita cost of treatment in the four state institutions for mental defectives from $178.33 to $407.93, the latter being a state school for the feebleminded.

New York Electrotherapeutic Society.—The fall meetings of this society begins October 7th, and will be held weekly, the meeting places will alternate between the New York Academy and the City Club, the first one being at the Academy.

Medical Study in Austria.—Physicians in good standing in the American Medical Association, who are going to Vienna to study, will be granted, on presentation of a written statement from the Association, a reduction of fifty per cent. in the Austrian visé fee.

Fund for Nutritional Education.—A fund of one hundred thousand dollars, payable in five annual installments, has been given by Mr. W. B. Ward, in behalf of the Robert Boyd Ward Fund, to the American Institute of Baking, for the establishment of a department of education in nutrition.

Toledo Service Bureau.—A service bureau has been established at the Toledo Academy of Medicine, financed by the academy as a humanitarian service. During the first month there were nearly three thousand telephone calls, mainly by patients wishing to locate their physician.

Addition to Mount Sinai Hospital.—A nurses' home accommodating 480 nurses, with a training school, is to be built in connection with Mount Sinai Hospital, New York. The building will be fourteen stories high, and there will be connections by tunnel with the various other buildings of the hospital. The estimated cost is two million dollars.

Pittsburgh Medical Centre.—The University of Pittsburgh has announced plans for a $14,000,000 medical centre, to include Presbyterian, Children's, Elizabeth Steele Magee, Montefiore, and the Eye and Ear Hospitals, with a combined capacity of 1350 beds, and also a $2,000,000 medical unit.

Police and Fire Surgeons to Meet.—The fourth annual convention of this organization is to be held October 6th and 7th, at Grand Rapids, Michigan. One of the matters to be dealt with is the standardization of medical and physical requirements for civil service employees, especially the police and firemen in the larger cities.

Christmas Seals.—Plans are already being made for the eighteenth annual sale of the National Tuberculosis Association's Christmas seals. The organization is prepared to furnish copy for advertising and also brief articles for newspaper and periodical publication. The seal is of an especially attractive design.

Typhoid Fever in Ohio.—Reports of the state department of health show an increase of thirty-five per cent. in cases of typhoid fever, over a year ago. Water supplies are at the lowest level in three years, and in the most polluted condition ever known. There are two widely separated epidemics, one in Athens County in the southeastern part of the state and one in Wood County in the northwest.

American College of Radiology and Physiotherapy.—The annual meeting of this association will be held in Chicago, October 19th to 22nd. Dr. Curran Pope, of Louisville, Kentucky, is president of the society. Clinics will be held at three Chicago hospitals. Guest speakers at the meetings will be Dr. William Allen Pusey and Dr. D. J. Davis, of Chicago.

Association of Military Surgeons.—This organization will hold its annual meeting at the Waldorf-Astoria, New York, October 8th to 10th. Official delegates from eighteen foreign countries will participate. The program will include visits to West Point, Ellis Island, the Army Medical Supply Depot, the Naval Hospital and Medical Supply Depot in Brooklyn, the airdrome at Mitchel Field on the day of the Pulitzer race, the Rockefeller Institute and various hospitals, and a review of and demonstration by the 102nd Medical Regiment of the 27th Division.

Civil Service Examinations.—The U. S. Civil Service Commission announced examinations for junior medical officer, assistant medical officer, associate medical officer, medical officer, and senior medical officer, at entrance salaries from $1,860 to $5,200, with advancement from $2,400 to $6,000. Applications will be received until December 30th, blanks may be obtained from the U. S. Civil Service Commission, Washington, D. C.

The U. S. Public Health Service announce examinations for entrance into the regular corps of the service, to be held December 7th, at Washington, Chicago, New Orleans, and San Francisco. Information may be obtained from the Surgeon General.

Rural Hospitals.—With the purpose of improving rural medical nursing and hospital care, the Commonwealth Fund of New York is offering to assist in the buildiing of one hospital in a rural section. Certain conditions are laid down governing the distance from existing hospitals, number of physicians for staffing the hospital, character of highways and transportation lines, willingness and ability of the community to defray deficits from operation. The fund offers to pay two thirds of the cost of construction and equipment.

If the experience in building one such hospital seems to warrant an extension of the program, the fund will consider making a like offer to other districts needing a hospital. Applications are now being received, and considered. It is probable that a decision as to the first unit will be made in the early fall.

Postgraduate Courses in New York.—The Beth Israel Hospital announces postgraduate courses in diseases of the heart and arteries, in charge of Dr. Morris H. Kahn, to be given between October 5th and December 11th.

New York University and Bellevue Hospital Medical College announce a three weeks' course in ophthalmology to be given by Professor Basil Graves, in October. A three weeks' course in regional anesthesia as applied to general surgery will be given during October, December, February, and April, by Gaston Labat, formerly of the Mayo Foundation.

Columbia University announces eight weeks' courses in general medicine, dermatology, pediatrics, gynecology, neurology, ophthalmology, otology, surgery, and surgical pathology, to be given at Mount Sinai Hospital. The first series will last from October first to December first. Information may be obtained from Mount Sinai Hospital. Similar courses in neurology and psychiatry, to be given in other institutions, are also planned; application should be made to the medical school of Columbia.

Personal.—Dr. William D. Haggard, president of the American Medical Association, was principal speaker at the meeting of the Northwest Alabama District Medical Association, held at Decatur, Alabama.

Dr. John L. Kantor, of New York, has moved his office to 145 West Eighty-sixth Street.

Dr. Byron Sprague Price, of New York, has moved his office to 43 East Fifty-third Street.

Dr. August M. Sartorius, of Jersey City, has sailed for two months in Europe.

Dr. Gabriel J. Kraus, of Philadelphia, has been honored by the Order of Haller Swordsmen from the Polish Government in recognition of his services during the war.

Dr. James D. McKinnon and Dr. Edgar R. Maillard have been appointed assistant pathologists to the New York state department of health laboratories.

Dr. Robert T. Frank has located at 10 East Eighty-fifth Street, New York. He is now gynecologist to Mt. Sinai Hospital of New York.

Dr. Emmanuel Giddings, who was physician in charge of Willard Parker Hospital and is now physician in charge of Riverside Hospital, has been appointed superintendent of the Reconstruction Hospital, and assumed his new duties October 1st.

MEETING OF THE CANADIAN MEDICAL ASSOCIATION AT REGINA, SASKATCHEWAN

The fifty-sixth annual convention of the Canadian Medical Association opened at Regina, Sask., on June 28th. The attendance was fairly good, among those present being Mr. H. W. Carson, F.R.C.S., senior surgeon of the Prince of Wales Hospital, Tottenham, London, England. At a luncheon given in honor of the visiting medical men, Dr. J. G. Fitzgerald, of Toronto, contrasted the progress made in Canada in the war on tuberculosis with that reached in Denmark, one of the most advanced countries in the world in this field. Much was being accomplished in Canada, and medical men here had contributed much toward the fight against the dread scourge. In Denmark, however, even greater advance had been made, and this little country, the speaker asserted, was today showing the way to the rest of the medical world in the encouragement of fundamental researches. Denmark boasted of a foundation for the maintenance of scientific laboratories in Copenhagen, which during the past ten years had contributed greatly to the advancement of knowledge in physics, physical chemistry and other scientific subjects.

A grant of $30,000 to carry on postgraduate extension lecture courses throughout the length and breadth of Canada from the Sun Life Insurance Company of Canada has been accepted by the Canadian Medical Association Council. According to the provisions of the grant, the association will control and manage the details of the organization and the development of the service, which will be chiefly directed toward helping the rural medical man to keep abreast of the advance in medicine.

A report on medical education submitted by Dr. D. J. McLean, of Winnipeg, expressed the need for a course in medical schools to be directed toward turning out general practitioners fully qualified to render a public service, rather than purely scientific men. A report on interprovincial relations laid stress on the importance of standardizing the preliminary education for medical students and the need for a uniform standard of licensure. Dr. T. C. Rontley, of Toronto, secretary of the association, announced that negotiations had been opened with the Royal College of Surgeons in England whereby in future members of the Canadian medical profession might obtain membership in the college.

Hailed as the greatest contribution to medical science, the discovery of insulin, the advance of experimental work in connection with the thyroid gland, were outlined by Dr. J. P. Collip, University of Alberta, in a scientific address. Dr. Collip, who was associated with Dr. Banting and Dr. Best in the perfection of insulin, dealt with the physiological significance of the extract with which it is hoped ultimately to effect some cures of serious complications resulting from certain operations affecting the thyroid glands. The researches so far, he explained, had been confined to experimental work upon animals, particularly upon dogs. A peculiar form of convulsion had been associated with operations on these glands. By injection of the new extract these severe symptoms could be completely controlled, so long as regularly administered. Dr. Collip stated definitely that the extract had not been used in the treatment of human patients, adding that clinical use of the remedy would of necessity have to be carefully worked out before it could be safely administered to a human subject. But, he asserted, results obtained already gave rise to high hopes for such cases suffering from these hitherto severe and untreatable symptoms. The extract, the speaker explained, was obtained from the ox.

Dr. Charles Hunter, associate professor of clinical medicine, University of Manitoba, stated that a large percentage of the sickness assailing mankind throughout the world was directly attributed to the state of mind and that a great deal could be accomplished in overcoming this condition by the correlation of psychotherapy and medical science.

Mr. H. W. Carson, F.R.C.S., London, stated that cancer, dependent upon its situation, was absolutely curable, provided that treatment was applied in the early stages of the disease. He maintained that surgery was the only safe method to be used in incipient cases.

Dr. M. M. Seymour, Deputy Minister of Health for Saskatchewan, foreshadowed the day when communicable diseases would cease to be a menacing problem to mankind.

A keener appreciation of the work carried on by the research worker was the gist of the remarks by Dr. J. G. Fitzgerald, director of the Connaught Laboratories, Toronto.

Dr. Stuart Pritchard, of Battle Creek, Mich., emphasized the point that tuberculosis was not nearly such a menace to civilization as was popularly imagined. Tuberculosis, he said, was now known to be a curable disease, and the dangers of infection from contact were considerably exaggerated in respect of the adult. Children, however, were more subject to infections.

MEETING OF THE FIFTH BRITISH CONGRESS OF OBSTETRICS AND GYNECOLOGY IN LONDON

At the house of the Royal Society of Medicine, I Wimpole Street, London, the fifth British Congress of Obstetrics was held April 22d, 23d, 24th and 25th. The president was Dr. H. Russell Andrews of London and the secretaries Dr. Clifford White and Mr. John D. Barris of London. The meeting was well organized and managed and there was a good attendance. Several Americans and Canadians were present, among them Dr. Franklin Martin, of Chicago. The papers read were of a high standard and the question of puerperal sepsis from various aspects was considered. In Great Britain puerperal sepsis causes much mortality and its etiology is still a matter of doubt. The first paper read was by Sir Ewen Maclean, professor of obstetrics and gynecology in the Welsh National School. He dealt with the condition in Wales at length and emphasized the pressing need for better houses and more health visitors, trained midwives, maternity homes, and hospitals.

Dr. Gibbon FitzGibbon, master of the Rotunda Hospital, Dublin, and Dr. Joseph W. Bigger, pro-

fessor of bacteriology in the University of Dublin, read an account of an investigation into the etiology of puerperal sepsis.

Swabs were collected from the vagina before and after delivery and from the uterus after delivery in fifty normal women. In all 158 swabs were examined and streptococci were present in 101. Only two of these were of the hemolytic variety, the rest being nonhemolytic. Fifty-four per cent. of the postpartum uteri examined contained streptococci. In a further series, in which particular care was taken to prevent vaginal contamination, twenty-eight per cent. were found to contain streptococci.

Mr. Leonard P. Lockhart described bacteriological examinations, in one hundred consecutive admissions to a lying in ward, of the cervix and vagina during pregnancy, with special reference to hemolytic streptococci. It is asserted that the series is of sufficient size to justify the following conclusions: 1. The presence before labor of streptococci in the genital passages of a pregnant woman is a potential source of danger. 2. This danger is increased if labor is abnormal. 3. All types of streptococci may cause pyrexia, especially the hemolytic variety. 4. Ward infection is not held to be the cause of the majority of hospital cases of puerperal pyrexia.

Dr. Bethel Solomons, gynecologist to Mercer's Hospital, Dublin, gave the results of a questionnaire on the subperitoneal Gilliam operation performed during the past six years by Dr. Solomons. The chief reasons for the production of this paper were 1, the divergent views held with regard to the treatment of backward displacement; 2, to show that there are many symptoms dependent on the displacement; 3, to find out if these symptoms are relieved by the operation; 4, to obtain knowledge as to pregnancy after the operation, and especially if there was difficulty in labor; 5, to find by examination if the uterus remained in the suspended position, and if there were any untoward symptoms following the operation.

The operative measures employed by Professor W. W. Chipman, of Montreal, for prolapsus uteri were described by him. The operation employed in Montreal consists in the exposure of the fascial cleft, the replacement of the viscera, and the radical cure of the hernia. Professor Chipman believes that as well as being a simple operation it is anatomically sound, and in Montreal during the past ten years has given satisfactory results.

Dr. Wilfrid Shaw read a paper on the relationship between ovulation, corpus luteum formation and menstruation. In the course of his investigation of this subject, the endometrium and ovaries of women who were menstruating regularly were examined. The date of occurrence of the earliest premenstrual changes was found. The ovaries were examined for early corpora lutea and the date when ovulation occurred was deduced from this investigation. The structure of the corpus luteum was examined and the changes taking place during menstruation and pregnancy were followed. It was shown that a relationship existed between the maturity of the corpus luteum and the development of the premenstrual changes. Degeneration of the corpus luteum was found to occur during menstruation.

Mr. Malcolm Donaldson read a paper on the treatment of inoperable carcinoma of the cervix with radium. The paper dealt with the technic employed in treating carcinoma of the cervix with radium, including methods of application per vaginam and per abdomen. The results published from various centres were quoted. The main part of the paper was devoted to clinical observations on eighty-five inoperable cases treated with radium. In addition to this, there are conclusions based on the histological sections obtained from hysterectomies performed subsequently to irradiation of the cervix. The conclusions came to were as follows:

1. In the vast majority of cases—eighty-five per cent.—hemorrhage disappears entirely within a few weeks, and if it returns at all, does so a short time before death. 2. In sixty-three per cent. of cases ulceration cleared up entirely, either temporarily or permanently. 3. Of those cases in which cauliflowerlike growth was present, in seventy per cent. it disappeared entirely. 4. The duration of life is prolonged in a certain number of patients. 5. The general condition of the patient in the majority of cases is much improved, and in numerous cases they were able to do their work in comfort for many months.

Dr. Gilbert I. Strachan, of Cardiff, read a paper on the treatment of carcinoma of the cervix by radium. In this paper he stated that about forty cases of carcinoma of the cervix had been treated and the clinical and histological results observed. The technic of radium application was described and the contraindications noted together with the points to be observed during the application. Clinically the conditions of the patients at the time of radiation and when last examined were stated, together with those who were known to have died or had failed to report. The histological changes in the carcinoma were described and general conclusions drawn regarding the efficacy of radium treatment in this condition.

Dr. A. Louise McIlroy and Dr. G. Pillman Williams contributed a paper on the toxemias of pregnancy from their clinical and chemical aspects. Dr. McIlroy read the paper. It described clinical and chemical methods of examination, the chemical examination of the blood and urine in normal pregnancy, toxemias without albuminuria, vomiting, headaches, antepartum hemorrhage, edema and abortion, albuminuriæ, nephritis, cystitis and pyelitis, other albuminurias, clinical significance of symptoms and signs of toxemia, chemical significance of examination of blood and urine in toxemia, results of toxemia upon the ovum and fetus.

Dr. John H. Teacher, of Glasgow, gave a lecture with lantern demonstration on the implantation of the human ovum. The principal points dealt with were: 1, The close of the decidua capsulans and the nature of the closing mechanism; 2, the relations between the maternal bloodvessels and the ovum in the earliest known stages; 3, theoretical considerations related to the nutrition of the ovum prior to implantation and the process of implantation.

Papers of great medical and scientific interest were read by Professor Whitridge Williams, of the medical department of Johns Hopkins University, and others.

Book Reviews

SURGERY

Chirurgische Operationslehre für Studierende und Arzte. Von Prof. Dr. Friedrich Pels Leusden. Vierte, wesentlich verbesserte Auflage. Mit 771 Abbildungen. Berlin and Wien: Urban & Schwarzenberg, 1925. Pp. xvi-832.

In this the fourth edition the plan of the previous editions has been followed and numerous additions have been made. Although the book is intended for the use of students and practitioners, it is most suitable for students, both as regards the subject material and the style of presentation.

The chapter on antiseptics and asepsis is excellent. The section on anesthesia leaves much to be desired. The subject of rectal anesthesia is omitted entirely. Local anesthesia is well presented but little mention is made of regional anesthesia which promises to become an important branch of anesthesia. Chloroform seems to be looked upon with much more favor in Germany than in this country.

The subjects of the cutting and reuniting of tissues, vascular surgery, and operations on the extremities, the head, neck, thorax, and the abdomen, and finally, the chapter on the urinary and sexual organs are presented in a didactic manner. Only one type of operation is generally described for each procedure, but this after all is probably the best way to teach students. In bone surgery, the motor drill is not mentioned, the author still preferring hand driven instruments. Tonsillectomy seems to be preferred by the author to tonsillectomy and only the old Matthieu tonsillotome is described. The former is the routine operation recommended. Of prostatectomies, only the Freyer method is described.

Numerous other examples of such onesidedness might be mentioned. The book has an air of extreme conservatism. As far as it goes it might do for German medical students, but the American would certainly not be satisfied with it. The illustrations are numerous but are of the old style of schematic drawings mostly. We are accustomed to more pretentious illustrations and photographs.

VITAL CAPACITY OF LUNGS

The Vital Capacity of the Lungs. A Handbook for Clinicians and Others Interested in the Examination of the Heart and Lungs Both in Health and Disease. By J. A. Myers, M.S., Ph.D., M.D. With an Introduction by S. Marx White, M.D., F.A.C.P. Baltimore: The Williams and Wilkins Company, 1925. Pp. 140.

Although Hutchinson, in 1846, established the technic and all the important physiological data of the vital capacity of the lungs, the subject received little attention until the last ten years, during which time a voluminous literature on this topic has appeared. In this small monograph Dr. Myers, who has devoted considerable study to this subject, has ably and succinctly summarized all the important old and modern contributions, and has emphasized the chief facts resulting therefrom. In separate chapters he discusses the physiological variations of the vital capacity, the influence of disease upon the vital capacity, the limitations and uses of the test and matters of technic. Simple tables enabling one to calculate the variation from the normal as correlated with height, weight and surface area are included. A bibliography of over two hundred references adds greatly to the value of the book. There are more typographical errors than seem justified for so small a volume. On page 28 there is incorrect reference to Table 6, Chapter VI; on page 66 one reads "statis" for stasis, and on page 86 the last line is completely misplaced.

Many will doubt the practical utility and necessity of repeated tests of vital capacity in the diagnosis and treatment of pneumonia as recommended by Dr. Myers, as well as the statement—"The time is at hand when all persons should know their actual vital lung capacities, just as they should know their actual heights and weights." The cases which Dr. Myers cites as illustrative of the value of the vital capacity test in preventive medicine are hardly conclusive, for in every instance the diagnosis of disease was made before the reduction in vital capacity was discovered. This enthusiasm of the author, of course, does not detract from the value of the vital capacity test, chiefly as a functional test for the sufficiency of the circulation.

GONADAL SECRETIONS

The Internal Secretions of the Sex Glands. The Problem of the Puberty Gland. By Alexander Lipschütz, M.D. With a preface by F. H. A. Marshall, F.R.S. Cambridge: W. Heffer & Sons, Ltd. Baltimore: Williams & Wilkens Co., 1925. Pp. 503.

Lipschütz's book is not a translation of his original publication in 1919, *Die Pubertaetsdruese und ihre Wirkungen,* but he has entirely rewritten the work in English, with the result that he has created the most complete and thorough exposition that exists regarding this subject. Hardly any question is left unanswered that a physician, a biologist, a psychologist or even a layman may ask in connection with the functions of the sex glands. Lipschütz is cautious in all his conclusions. He sharply differentiates between ascertained facts and between attractive, though unproved theories. This differentiation is especially emphasized in regard to the results of castration.

Lipschütz has not only studied and recorded the work of others in his book but also reports at length the numerous and valuable experiments which he, himself, and his coworkers have carried out. The function of the sex glands have been studied by attempting to overcome the consequences of castration. For this purpose, transplantation, as well as feeding and injections of gland extracts, were employed and the result noted. A chapter is devoted to the study of the connection between the internal secretion of the sex glands and the nervous system. The question of the seat of production of the internal secretion of the testicle is decided for mammals as follows:

a. The interstitial cells are the necessary part of the endocrine apparatus of the testicle.

b. No proof exists of a direct hormonic action by the cells of Sertoli or by other constituents of the wall of the tubules independently of the interstitial cells.

Less definite conclusions are reached as far as the

seat of production of the internal secretion of the ovary is concerned. Lipschütz says, "It is highly probable that the internal secretion of the ovary of the mammal is elaborated partly by the cells of the membrana granulosa and partly by cells of the theca interna. It is difficult to decide whether the increased internal secretion of the ovary is caused by a proliferation or only by an activation of the endocrine cells."

Chapters are devoted to the study of the specific sex action of the testicular and ovarian hormones, to the question of the isolation of the active principles, to the importance of the seminal vesicles and the prostate gland and to intersexuality, in which chapter hermaphroditism, homosexuality, etc., are thoroughly discussed.

The last chapters deal with eunuchoidism, sexual hormones and morphogenesis and the problem of rejuvenation. The book is richly illustrated and contains a most complete bibliography. The author should be congratulated to this splendid achievement.

SURGICAL CLINICS

The Surgical Clinics of North America (Mayo Clinic Number, June, 1925). With 115 Illustrations. Philadelphia and London by W. B. Saunders Company. 260 pages.

Twenty-eight members of the Mayo Clinic contribute the twenty-three clinics which constitute this interesting volume. W. J. Mayo contributes the first clinic on filtration phenomena in Relation to Clinical Medicine, a most interesting and instructive study, and C. H. Mayo follows with a brief article on Ulcer of the Stomach and Duodenum. Judd, Parker and Morse discuss urinary and prostatic calculi rather extensively, and point out the important but little known fact that severe pain is the predominating complaint in these conditions in only about 30 per cent. of cases. Cases are cited in which nothing more than a dull ache, often spoken of as "backache," was the only symptom recognized by the patient. Empyema is fully treated in a clinic by Harrington and Plankers.

The illustrations and the typography in general are of the high order which always characterize this series of useful publications.

DIABETES

Diabetes; Its Treatment by Insulin and Diet. A Handbook for the Patient. By Orlando H. Petty, A.M., M.D., F.A.C.P., and William H. Stoner, A.M., M.D., F.A.C.P. With Illustrations and Tables. Philadelphia: F. A. Davis Company, 1925. Pp. 133.

Here is another good handbook for the patient suffering from diabetes. The author emphasizes that it is not intended as a substitute for the physician, but as a valuable aid to the patient in that it explains fully the meaning of diabetes and how the diabetic patient may keep himself in the greatest efficiency.

This second edition includes many new sections, notably those dealing with the early diagnosis, the prevention and the treatment of complications of diabetes. Several minor numerical errors of the first edition have been corrected. More complete normal weight tables and index have been introduced and the salt free diet in the treatment of hypertension is discussed more fully. The following subjects are taken up: The inorganic salts and vitamines in foods, the manner of weighing and measuring foods, the methods of estimating diets, uranalysis (glucose), insulin and the technic of its administration in the home, and diabetic hygiene. A number of recipes are given and also tables of the protein, fat and carbohydrate content of the commonly used foods.

In a foreword, John B. Deaver urges closer cooperation between the internist and surgeon in the handling of surgical conditions in diabetics.

THE DIGESTIVE MECHANISM

Handbuch der Biochemie des Menschen und der Tiere. Herausgegeben von Prof. Dr. Carl Oppenheimer. Zweite Auflage: Leiferung 16, Band V. (S. 1-160), Bog. 1-10; Lieferung 17, Band IV (S. 353-544), Bog. 23-24. Jena: Gustav Fischer, 1924.

These sections of Oppenheimer's *Handbuch* are devoted to digestion and the conditions of resorption of the products of such action in both the lower animals and the vertebrates. The chemistry of the nervous system, of the eye, of tumors, salivary glands, and the gastric juice is also considered. As usual, the articles are complete and quite satisfactory from the point of view of a reference book. The different writers are not always critical in the material which they select for inclusion, but leave much to the reader's discretion.

BACTERIA AND CANCER

Le Bactériophage de d'Hérelle. Par Docteur Paul Hauduroy. Préface du Professeur Fernand Bezançon. Paris: E. François, 1925. Pp. 212.

This small monograph on the bacteriophage supplements d'Hérelle's book published several years ago. It furnishes an admirable résumé of this little known subject, now so interesting because of the possible connections between these minute parasites and the etiology of cancer. Levaditi and others have been working on this phase of the question, and the recent newspaper announcements from England of the investigations of Gye on the same subject show that there is some possibility that ultimately we shall know much more than we do at present of some of the obscure diseases, including cancer. The author is careful to point out, however, that the amount we do know is extremely small, and that the greatest care must be used in drawing conclusions concerning the pathogenicity of an organism which cannot be seen when it is cultivated, and is purely a parasite of tissue cells. Assumptions are dangerous, and the writer himself gives an admirable example of scientific restraint in the expression of his opinions.

EAR, NOSE AND THROAT

Diseases of the Ear, Nose and Throat. By Harold Hays, M.A., M.D., F.A.C.S. Illustrated with 495 halftone and line engravings in the text, and 55 full page plates, nearly all in color. Philadelphia: F. A. Davis and Co., 1925.

We are fully aware of the difficulties that beset the specialist who attempts to popularize his subject for the benefit of the general practitioner: it requires delicate discrimination to place before the latter only what is essential and of practical service in his everyday work, thus avoiding the pitfalls of cumbersome theorizing and frequently the not quite honest padding. Few authors succeed in overcoming these difficulties, and while the present one has not fully conquered them he has nevertheless succeeded in

presenting to the profession a work of distinct interest both to the general practitioner and to the specialist.

In the section on the ear we call the reader's attention to the chapter on progressive deafness (a subject to which the author has devoted considerable time and energy in a medicosocial way) which is most illuminating and important, the more so as the majority of the textbooks either skim over the subject in a perfunctory manner, or neglect it altogether. The same, with some reservation, may be said of the chapters on diseases of the external ear and of acute and chronic otitis media. But it is questionable whether "the average medical man who desires to round out his learning and perhaps do something along the lines of treatment" (from the author's preface) will profit much by a painstaking description of the mastoid operation, or a detailed account of the examination of the internal ear, this latter procedure being beyond the thorough grasp of even many a professed specialist.

The subject of diseases of the nose and throat is brought up to date and gone into quite thoroughly, every operative procedure of any importance being fully presented in a way to be grasped by the general practitioner, and at the same time presenting sufficient interest to the practising laryngologist. It might be advisable, however, to devote more space to the larynx, and especially to tuberculous laryngitis, a subject of considerable importance to the general practitioner into whose hands the patient often comes long before he reaches the specialist.

PHYSIOTHERAPY

Lectures, Clinics and Discussions on Electrophysiotherapy. Physiotherapeutic Lectures, Second Edition. Chicago: H. G. Fischer Company, 1925. Pp. 740.

This book represents lectures and clinics given by two dozen contributors during a five day convention held under the auspices of physiotherapeutic manufacturers.

As always in the expression of many individual viewpoints in condensed form the different aspects of a vast and as yet unstandardized field, including both subject and technic, many statements must be recognized as representing only the personal opinion of their author.

On the other hand, there are many valuable suggestions and more or less detailed descriptions of technic in many phases of physiotherapy and though the different aspects of the subject are widely scattered through the book it conveys in all a rather gratifying attempt at meeting the generally accepted technic.

For the amateur the dangers of misguidance are considerable. For one who has practical knowledge of the basis for physiotherapy and is so able to differentiate and assimilate intelligently, but having limited experience, the book ranks above the average of physiotherapeutic compilations.

The ground is fairly well summarized, though necessarily fragmentarily and partially, and deals with many of the electrotherapeutic modalities. However, some of the most useful even of these are not referred to.

Authors of rank outline numerous practical features and some excellent points are brought out. Many of these are expressive of the writer's personal experiences rather than being a repetition of theories. Many named diseases and diagnostic points are discussed to advantage and mostly from a clinical point of view. Considerable rationale for treatment is included.

Physiotherapy in relation to all of medicine and to its industrial economics is outlined. The factors most strongly set forth are surgical and medical diathermy and the actinic rays. Under the latter some pertinent points are cited which guide or influence the therapist in the current technic.

A rather comprehensive survey is given of high potential x ray deep therapy which outlines the present day viewpoint. This article follows the rule of the day in being optimistic to an unwarranted degree. It gives no hint at abatement of the extravagant outlook for massive doses.

The book has many excellent features. In some respects it further tends to decrease the unwritten void in the relation of physiotherapy to medicine as a whole. For the physiotherapist already fairly well grounded the book should find a welcome reception.

Medicoliterary Notes.

The name of the Massachusetts School for the Feebleminded has recently been changed to the Walter E. Fernald State School, as a tribute of the late Dr. Walter E. Fernald, who was its superintendent for nearly forty years.

* * *

The July issue of the *American Journal of Public Health* contains a series of articles on periodical health examinations. These are A Survey of the Present Status of the Periodical Health Examination, by Dr. Alec N. Thompson; The American Medical Association and Periodical Health Examinations, by Dr. John M. Dodson; Health Examinations Past and Present and Their Promotion in Pennsylvania, by Dr. Elliott B. Edie; and The Place of Health Examinations in the Practice of Medicine, by Dr. Alec N. Thompson.

Bubonic plague was first recorded as occurring in A. D. 542 in Pelusium, Egypt, having spread by trade routes over the then known world, until, at its height, the mortality was from five thousand to ten thousand persons a day.—*Dearborn Independent.*

Apparently one of the results of the Scopes trial has been the organization—or possibly only an instigation toward the organization—of a new society to be known as the Science League of America. This is announced as a nonsectarion, nonpolitical association formed to protect scientific freedom, to combat the attacks of "fundamentalists," and to foster opportunities for scientific work of all kinds. California is the birthplace of the new organization.

If innovations and legal enactments can make a civilization, the new Turkey is certainly highly civilized, so that there need be no surprise at the information from Constantinople that the government is encouraging the use of surnames. At present only a few hundred Turkish families have surnames, but those who are without are now permitted to choose for themselves, provided they do not infringe on the family copyright of some famous person. Now that the surname has arrived in Turkey, it is obviously going to be treated with considerable respect, for apparently it has to be placed before all other names, which is the system adopted by directories and other businesslike and severely secular compilations. But in this matter the Turks are still lagging behind a near neighbor, for it is not long since we were assured that Soviet Russia had become so extremely

methodical that nothing except surnames were to be allowed and that the individual bearers of them were to be distinguished by numbers, like full privates in the British army. If that scheme was ever seriously proposed at Moscow it seems to have been dropped—perhaps the Amalgamated Union of Operative Russian Novelists protested on the ground that their works would lack all authentic atmosphere if they were not allowed to call the same character by three or four different names inside the same chapter.—*Manchester Guardian Weekly.*

The issue for July 3d of *Public Health Reports* contains a very complete and useful chronology of the development of Federal health legislation and public health and medical activities, compiled by James A. Tobey of the Institute for Government Research, Washington.

* * *

A presidential decree in Mexico has recently provided for the establishment of a Federal Bureau of Child Welfare with local branches throughout the country. This bureau, which will be subsidiary to the Bureau of Education, will be interested in all children, regardless of race or social status. Its activities will be concerned chiefly with the compilation of all laws on child welfare, the drafting of new laws for the protection of children, and the establishment and supervision of child welfare institutions.

The cornerstone of the Potts Memorial Hospital, one of the first institutions in this country to be devoted to industrial rehabilitation of the tuberculous as well as to their care and treatment, was laid on June 26th at Livingston, New York. The institution will be constructed upon an estate comprising seventy-six acres, and which has already farm buildings, live stock, and a large grove and gardens. It is hoped that it will be ready for occupancy by April of next year.

Barnacles on bottoms of vessels collect only on surfaces painted blue and black, according to a discovery recently announced by the U. S. Bureau of Fisheries. White, yellow and green plates are practically free from them.

* * *

Articles of special interest in the August number of the *American Journal of Public Health* are The Part of State Health Departments in School Hygiene Programs, by Dr. Eugene R. Kelley, and The Rôle of the State in Industrial Hygiene, by Dr. Emery R. Hayhurst.

* * *

The American Pharmaceutical Association has recently announced that medicine gardens as adjuncts of schools of pharmacy are to be fostered by it, as a means of supplying to classes in botany and microscopy proper materials for study.

* * *

A new, nonasphyxiating illuminating gas is being promoted, according to statements recently made to the press by the Bureau of Standards. This gas is made either from oil or from refinery residuum of oil refineries, and is nonasphyxiating because it is manufactured at a temperature much lower than the temperature which is necessary for the production of carbon monoxide and carbon dioxide. It is composed largely of hydrogen and carbon combinations.

The number of suicides has of late increased so rapidly in Germany that an Antisuicide Bureau has recently been established in Berlin to help men and women to find "another way out." It is reported that already more than eight hundred persons, more than half of them men, have called at the bureau for help and advice. According to German official records, in 1921 there were 12,764 suicides among men and women in the country. This amounted to 20.7 per 100,000 of the population, a rate equalled by no other country in the world.

Dr. W. E. Gye, who, with Mr. J. E. Barnard, has made a very important cancer discovery, is only forty years of age. He is a Derbyshire man, and began life, I believe, in commercial work. His name originally was Bulloch, and he afterwards changed it to Gye. In early life he received a bequest which enabled him to qualify at Edinburgh University. While at Edinburgh he came under the influence of Dr. Russell and became interested in cancer research, and worked in this field until the outbreak of the war, when he joined the forces and served as a doctor. After the war he took up cancer investigation again, and worked with Dr. Murray, the well known worker in cancer research. Later Dr. Gye became one of the investigators working under the Medical Research Council, and the work of the past two years which has resulted in this discovery has all been done under the control of the Council. Dr. Gye is described by his friends as a retiring man, absorbed in his scientific work and reluctant to talk about it. The fact that his inquiries were leading him to a highly important new piece of knowledge has been known to him for some time, but his dislike of premature discussion has prompted him to say very little about it, and to withhold information until the discovery was sufficiently confirmed by exhaustive testing and experiment.—*Manchester Guardian Weekly.*

Abstracts from Current Literature

SURGERY

Surgical Treatment of Duodenal Ulcer.—Charles A. Pannett (*Lancet,* March 14, 1925) asserts that there can be no reasonable doubt that in the evolution of the treatment of duodenal ulceration surgery is only a temporary expedient, but neither can it be denied that, in the present state of knowledge, operative treatment is able to confer upon the sufferer that relief which medicine is unable to bestow Gastrojejunostomy is a method which effects a cure in about seventy per cent. of cases reported by the author. These results do not show the operation in as favorable light as revealed by other statistics in England and America, based on very large series, but they agree with those reported from European clinics. The direct method of attack, as in the analogous gastric lesion, is likely to prove more effective in treatment if it can be carried out free from serious risk to the patient. In the cases of duodenectomy reported by the author results have been satisfactory, but the later clinical history of these patients remains for further study. This limited experience is favorable enough to justify a continued trial of duodenectomy in the treatment of duodenal ulcer.

Surgical Treatment of Gastroduodenal Ulceration.—Charles A. Pannett (*British Medical Journal,* March 14, 1925) draws the following conclusions regarding the surgical treatment of gastroduodenal ulcerations:

1. The primary treatment of gastric and duodenal ulceration is always medical.
2. Surgery is indicated when medical treatment has failed, or in recent cases when a large ulcer is demonstrable by x rays.
3. It is probably true to say that medical measures can be continued with advantage longer in duodenal than in gastric ulceration.
4. For ulcer of the lesser curvature away from the pylorus, sleeve resection is the operation of choice.
5. For ulcers of the lesser curvature close to the pylorus or ulcers at the pylorus, excision of the affected portion of the stomach, including the sphincter, followed by axial union, is the best.
6. For cicatrized pylorus following healed ulcer, pylorectomy is preferable, but gastrojejunostomy gives very good results.
7. For ulcer of the duodenum it is not decided yet whether resection of the duodenum with its attending increased risks gives results so much better than gastrojejunostomy that it should replace the shortcircuiting operation.

Surgical Treatment of Chronic Ulcerative Colitis.—Thomas Carey Evans (*British Medical Journal,* January 31, 1925) states that cases of colitis persisting over two or three months without intermission and with profound emaciation and anemia which do not respond to medical treatment should be handed over to the surgeon. When they reach this stage they are invariably examples of mixed infection, whatever the organism that caused the primary infection may have been. In severe cases the large intestine may be likened to an abscess or bag of pus. In all chronic cases a sigmoidoscopic examination should be made.

The only rational treatment, when the diagnosis is confirmed, is frequent irrigation of the large intestine, either through an appendicostomy or a valvular cecostomy, with eusol solution until the washings are clean; after that, with large quantities of warm saline for prolonged periods. Valvular cecostomy is particularly mentioned, as the closing of an ordinary cecostomy may be difficult later, besides being unpleasant for the patient and for those associated with him.

Femoral Hernia: Operative Treatment by Roux's Method.—In the fifty-two cases of Frank Harvey (*Lancet,* December 13, 1924), twenty-eight were in males and twenty-four in females. The youngest patient was a girl aged five and the oldest a woman aged seventy-two. Forty-six patients were traced and replied that the hernia did not recur and that pain was not complained of.

Roux's operation is a very simple one and is quickly performed. An incision is made parallel to the inner half of Poupart's ligament and along its lower border. The lower part of the incision is retracted so that the femoral canal is exposed. Omentum is often present and will usually be found to be adherent. All adhesions are freed, and it is frequently necessary to ligate and remove redundant omentum before returning it to the peritoneal cavity. Bowel, if present, is carefully examined where it has been in contact with the neck of the sac before it is returned into the abdominal caviety. The sac is pulled down with moderate tension, twisted to obliterate its lumen, and ligated high up, the redundant portion being excised. A rectangular staple, which is made in various sizes, is now taken, and its points passed through the inner portion of Poupart's ligament. The inner limb of the staple passes just internal to the crescent border of Gimbernat's ligament and the outer limb immediately internal to the common femoral vein. The staple is pressed firmly into the horizontal ramus of the pubic bone. Roux's punch is now placed on the staple, which is gently hammered into the bone until the crural ring is obliterated. Care must be taken not to drive the staple in too tightly, or Poupart's ligament will be torn. The external wound is then closed with silkworm sutures.

Studies in Biliary Tract Surgery.—J. H. Baldwin and W. R. Gilmour (*Annals of Surgery,* November, 1924) report as follows on their findings:

1. Cholecystitis may have its origin in vague beginnings in early life, but is clearly recognized and routinely treated in or past middle life. The average duration of clear cut symptoms was slightly over two years, while the average age of the patient in our series of one hundred and thirty consecutive cases was forty-four years.
2. Widespread, definite and troublesome adhesions with bands from gallbladder to duodenum and transverse colon were the most uniform finding in all types of cases.
3. Seventy-five cases were treated by cholecystectomy, with four deaths encountered from this series.
4. Forty-one cases were treated by drainage methods, with four deaths. Deaths in both series were due to cardiorenal failure or peritonitis in complicated stone cases.
5. The mortality percentage was 6.16 per cent.
6. In the followup data, the cholecystectomy cases were freer from symptoms and maintained their regained health more constantly.

Evidences of Regeneration in the Injured Elbow.—On the basis of five cases, Ernst Baumann (*Schweizerische medizinische Wochenschrift,* November 13, 1924) shows that after a fracture and a subsequent operation, the removed lateral condyle of the humerus regularly reforms by a true regeneration. As a result of the proportionate cooperative effect of osseous and articular regeneration there result relatively complicated regenerations, such as have been described in human pathology. The function of the five elbows was either absolutely perfect or injured to a slight extent, hardly worthy of practical consideration. Early articular function (functional stimulation) is given much credit for the regenerative process. Special emphasis is laid upon the fact that in the juvenile elbow the lateral condyle is regenerated from the metaphysis after the removal of the specific zone of growth.

If in one of the forms of fracture of the juvenile elbow the injured side is compared with the uninjured side, the former shows a considerable developmental outgrowth of the skeleton roentgenologically. Centres of ossification, which are still absent on the uninjured side, appear as large shadows at the site of the former injury. Centres of ossification present on both sides regularly appear larger upon the previously injured side. The union of the centres with each other and with the metaphysis shows corresponding differences. The posttraumatic acceleration of development first shows itself at a time when the posttraumatic vascular filling and the new formation of bloodvessels has undergone retrogression. It reaches its maximum probably after about two years, is somewhat retarded later on, but is still visible after years. The described acceleration of development is theoretically attributed to the universal property of living tissues of responding to injury (stimulation) with hypercompensation. Special emphasis is laid upon the position of adduction, which usually occurs in connection with well replaced and properly reduced supracondylar fractures in children.

Thoracoplastic Surgery in the Treatment of Pulmonary Tuberculosis.—William H. Thearle (*Colorado Medicine, March,* 1925), thus compares thoracoplasty with pneumothorax. Thoracoplasty presents the same general contraindications as any major surgical procedure—special contraindications are tuberculosis of intestines, miliary tuberculosis, organic nephritis, amyloidosis and no attempts at artificial pneumothorax.

Pneumothorax compared with thoracoplasty is a relatively safe procedure, free from shock and deformity; compression is gradually induced, which reduces to a minimum the dangers of aspiration as well as circulatory and respiratory disturbances. Pneumothorax possesses the great advantage that the lung can be released to some degree at least if trouble develops in the better lung.

The advantages of the immediate and permanent collapse of thoracoplasty are:

1. It obviates the long period of medical surveillance (three to five years, Gravensen) with its frequent refills necessary in pneumothorax therapy, which is associated with serious pleural effusions of variable degree in about fifty per cent. of cases (Alexander), purulent exudates in five per cent. to twelve per cent. (McKinnie, Matson), and spontaneous pneumothorax in 3.3 per cent. (Matson).

2. It produces a definite result in the poorer class, most of whom, Fishberg says, abandon pneumothorax refills prematurely, soon after discharge from sanitaria.

3. Lastly is the not uncommon danger of reactivation in an expanded lung after completion of a long period of pneumothorax therapy. It is often impossible to definitely predict when tuberculosis is permanently healed, even with negative clinical symptoms, and Alexander quite aptly expresses the cessation of pneumothorax compression as frequently "a jump in the dark."

Surgery of the Hand.—S. Bunnell (*Surgery, Gynecology and Obstetrics,* September 1924) gives in detail the various reconstructive methods and steps in surgery for the hand, accompanying them with cases. Following are the main principles he advises:

The wrist and fingers must first be put into functionating positions. That is, the wrist should be cocked up in extension and the fingers should be partially flexed and especially in their proximal joints. The thumb should oppose the fingers. A hand with a straight wrist, with extended proximal finger joints, and with the thumb at the side of the hand, is practically useless.

After trauma, infection, or operation the tissues are usually densely indurated. A second operation on such tissues will result in the summation of scar tissue and so had best be delayed a few months. The final result is not obtained until after the softening up process has taken place. This often takes a year. For most reconstruction, special splints must be used. These the surgeon himself should make to fit the case. They are usually made of metal. They should be boiled for application at the end of the operation. It is most important for later reference to make a complete record of a case before the repair is attempted. This should consist of photographs showing limits of motion, measurements of joint motion, condition of the bones, joints and tendons, amount of loss of nerve function, both motor and sensory, presence of contractures, degree of induration of tissues, and finally the strength and practical function of the hand.

Chiropodic Surgery.—G. B. Arana (*Surgery Gynecology and Obstetrics,* May, 1924) describes a technic for subungual hematoma which consists of double trephination and the making of a subungual passage through which anesthetics and antiseptics are caused to flow to empty and decolorize the hematoma. He recommends anesthetic before starting the operation only in the case of timid patients, as once the nail is perforated the subsequent proceedings do not cause pain. In draining, the stiletto must always be inserted between the under surface of the nail and the hematoma. If this is done pain is absolutely avoided. The author's cosmetic obduration technic follows:

When the hematoma has been extirpated in the manner described, the cavity must be well dried, and, for greater security, washed with serum, then with high proof alcohol, and lastly, dried with an air syringe as used in dentistry. The alcohol which may remain is evaporated, and the air vapor, contained in the cavity, dried. Dry and warm air is taken up from the flame by the proper syringe such as used by dentists, and expelled into the ungual cavity until the latter is apparently dry. Immediately thereafter the cavity is filled with the paste already prepared, which, to be efficaciously applied, must possess certain properties. As a matter of fact, it must be semifluid so as to enter into all the tiny spaces surrounding the cavity. It must be of a rosy tinge deeper than that which is normal to the nail, for through them the color is modified. It must solidify in a short time so that the filling may persist, and its temperature must not exceed that of the ungual body when applied.

After several tests, the author endorses the use of dressing seal or rose colored putty. As it dissolves in chloroform, we make a paste more or less fluid, at will, according to the quantity of solvent used. The cavity is filled by means of a common syringe which takes up the semifluid paste and drives it into the cavity through one of the orifices trephined in the nail. The other opening is left open so that the cement in entering the cavity expels the inside air.

The putty or cement must be pushed slowly in, until the air is wholly expelled; that is, until it comes out through the opposite ungual orifice. Then, closing the orifice with a tiny rubber piston and continuing to press in the paste, we raise the pressure within the cavity so that the paste will have to push into all the tiny free spaces.

Resection of Upper Maxillary.—E. E. Lauwers (*Surgery, Gynecology and Obstetrics,* October, 1924) offers a new technic for this operation. Its main objects are to avoid sectioning certain cutaneous muscles which affect the expression of the face and the play of the features, and to avoid leaving scars, the retraction of which often causes ectropion.

A vertical incision is made which splits the lower lip on the median line and descends to the mandibular symphysis, is continued along the lower edge of the maxillary to the angle of the jaw, then up along the posterior edge of the ascending branch to the lobe of the ear. The incision goes through the soft parts to the bone. The limits of the flap are marked and it is raised under the mandibular periosteum. The masseter is sectioned and great care is taken to maintain continuity with the periosteum. The lower gingivolabial cul-de-sac is entirely cut and the flap is thrown upward. The upper gingivolabial cul-de-sac is now cut from the curb of the lip to the retromolar space.

The anteroexternal surface of the maxillary is exposed and denuded close to the bone or under the periosteum according to the case. The infraorbital nerve is cut at the foramen. As the cutting proceeds the flap is raised higher forward and backward. A blunt retractor raises the entire contents of the orbit including the periosteum. Sharp instruments cut away the osteocartilaginous formation of the nose in front, and the molar bone at the back. The flap is then covered with compresses.

The remaining steps are absolutely identical to those which are described in the classical resection. The section of the maxillomolar attachment, the section of the ascending branches of the maxillary, the section of the palatal apophysis, and the severance of the pterygoid attachments present no particular difficulty.

Correction of Foot Arch.—J. T. Rugh (*Journal of Bone and Joint Surgery,* July 1924) recommends the soft tissue operation of fascia transplant, and says that the whole purpose of the transplant is the interruption of the continuity of tissues which are pathologic and which constantly tend to shorten as a result of the inherent changes arising from the underlying causative factors.

The technic is as follows: Beginning in front of the internal malleolus, a little higher or lower than the tibialis-posticus tendon (according to the height of the skin contraction), an incision is made transversely across the sole as far as necessary to free the skin shortening. The fascia is then cut and the flexor brevis and adductor hallucis are either overstretched or cut. If correction is not yet complete, the tibialis posticus and the flexor longus tendons are severed; the accessorius usually gives no truoble. If there still is resistance, a narrow bladed knife is slipped close under the astragalus, and the astragaloscaphoid ligament or any other underneath the foot arch is divided, and over correction is easily accomplished. Any bony deformity can also be dealt with after this time if it be found needful. The wound is packed firmly with gauze to check all bleeding and a plaster cast is applied to the foot to maintain it in over correction.

An opening is next cut in the inner and under side of the cast, of sufficient size to allow sewing of a graft in place. At a suitable height on the inner side of the calf of the

opposite leg, an elongated flap of skin, fat, and fascia is lifted, of sufficient width and length to easily cover the incision in the sole of the foot. The edges of the wound under the flap are drawn together by silkworm gut sutures and a pad of gauze is laid over the sutured incision. The sole of the involved foot is then approximated to the flap, the gauze packing is removed and the flap is sewn in place with silkworm gut, care being taken to secure accurate coaptation of skin edges. Copious dressings are applied all about the area and between the plaster cast and the calf of the leg, and an investing cast is applied to hold the two parts in firm position until union obtains. It is well to flex the knee of the host leg about and hold it so in plaster, as this position is more comfortable for the patient. After eighteen to twenty-one days, the cast is cut and the base of the flap separated from the leg and carefully folded into the outer end of the incision in the foot sole, which will have to be opened a little to receive it. This heals in a week, the cast being worn on the foot all the time, and the patient is then encouraged to begin walking. After another week, the cast can be removed and a proper shoe with a firm shank is fitted. The operation is simple and easy of performance and the results are good, if care is taken to entirely release the contracted soft parts and secure sufficient length and breadth of flap.

If the skin is not much shortened and the fascia and tendons are the main offenders, it is not necessary to transplant the skin flap, though the same principle of interposition of fat and fascia to interrupt the line of contraction is indicated and is accomplished as follows: A longitudinal incision is made in the sole of the foot, and the plantar fascia dissected out entirely, or in part, the tendons cut and thorough stretching done, and then a free fascial flap taken from the side of the thigh is transplanted into the sole of the foot in the place of the removed plantar fascia, and the incision closed. Plaster is then applied with as full correction as possible for a period of three to four weeks. Walking is begun in ten days or two weeks. This is followed up by massage and stretching for some time to insure thorough restoration of function in the sole of the foot, and a flatsoled shoe with firm shank will enable the foot to stretch from weightbearing and prevent buckling of the shoe from too great a muscle pull.

Correction of Burn Scar.—S. L. McCurdy (*Journal of Bone and Joint Surgery,* July 1924) describes the Z plastic method of operation for relieving deformity.

Split the burn scar from one end to the other at the crest. The two flaps thus made are dissected loose down deep into the tissues, even to the fascia over the muscles, where this is possible. The incision must be through the subdermal fat. Two incisions are now made from the two ends of this first incision, one to the right and the other to the left. The angle of these incisions to the first incision depends upon the part operated upon. The points of these two flaps are now dissected loose, always remembering to preserve the subdermal fat with the flap, if this is found. The joint is now extended and the flaps thus dissected loose very naturally drop into the denuded surface made by the extension of the extremity, or throwing backward of the head. It may be necessary to extend the lateral incisions farther out so as to permit the corners of the flap to drop back into the angles between the skin line. The corners of the flaps are now sutured in their new positions. It will be observed that the flaps cross each other in their adjustment to the new position.

Mechanism of Postoperative Hemorrhage.—A. O. Wilensky and S. S. Samuels (*Annals of Surgery,* November, 1924), finds strong evidence that infection is the most important single factor, if not the only factor, causing secondary hemorrhage in operative and other wounds. Their studies show that the presence of the drainage apparatus causes an apparently protective thickening of the wall of the vessel with which the drainage material is in close contact; that this thickening is due to a proliferation of connective tissue cells in the intima; that the infective process with resultant cell necrosis begins in the intima and spreads to the media; that a rupture occurs in the intima and media with the formation of an aneurysmal sac; and that the bleeding follows as a result of the rupture of the aneurysm. It seems, then, that in cases of secondary hemorrhage such as have been described, the important causative factors include an initial trauma of some kind, plus pressure of the tube or other drainage apparatus in an infected environment.

Resection of Twelfth Rib in Total Empyema.—C. Nather and A. Ochsner (*Surgery, Gynecology and Obstetrics,* July 1924) describes and explains his technic with the following conclusions:

1. Drainage of a pleural empyema at the anatomically most dependent portion is the method of choice. The physical and anatomical factors in drainage are more important than the physiological.
2. The position of the diaphragm in cases of empyema varies considerably before and after operation. Preoperatively it is impossible to determine what position the diaphragm will assume after the excavation of the exudate. Therefore it is safest always to drain at the most dependent portion of the pleural cavity.
3. The resection of the twelfth rib allows access to the pleural cavity at its anatomically most dependent portion.
4. A small pleural incision prevents the production of a large open pneumothorax. In those cases operated upon in the formative stage of the empyema before the mediastinum is fixed, there is no danger of a resulting mediastinal flutter.
5. By means of large, heavy, rubber drainage tubes with numerous lateral openings the pleural cavity can be completely drained independent of the position of the diaphragm.
6. Cases of empyema treated by resection of the twelfth rib have a shorter convalescence.
7. The formation of a chronic fistula is practically impossible because as soon as the infection has cleared up and the drainage tubes are removed the walls of the wound fall together. On the other hand partial resection of a rib produces a splinted wound the tendency of which is to remain open.
8. Total resection of a rib does away with the possibility of a resulting osteomyelitis of the rib and therefore one factor in the formation of a chronic empyema is eliminated.

Modification of Estlander's Operation.—E. D. Twyman (*Surgery, Gynecology and Obstetrics,* June, 1924), reports on the following modification to remedy in particular the defects of Estlander's operation, smallness of the mouth, or pouchiness of the upper lip and tension on the lower lip. The operation is performed under local anesthesia.

A triangle is outlined and cut from the upper lip at each corner of the mouth, its apex upward in the nasobuccal fold, its base downward and its lateral side prolonged downward and outward lower than the angle of the mouth. The nourishing pedicle left is attached to the lower lip, inner side. Additional room is had by a further incision extending outward in the line of the mouth. As the tension of the lower lip is released, the lower incision gaps open, a space is opened up into which the triangle of tissue from the upper lip naturally fits. Suture of the sides of the defect in the upper lip makes a natural looking line, the nasolabial for the mucosa is suitably sutured at the corners. Leaving the sustaining pedicle attached to the lower lip instead of the upper allows indefinite lateral extension of the os without endangering the nutrition of the triangle to be moved. Accurate measurement demonstrated in advance the gain that would be made.

Insulin in Diabetics Requiring Surgery.—Orlando H. Petty and William M. LeFevre (*Medical Clinics of North America,* November, 1924) propose the following emergency preparation for operations on diabetics: A catheterized specimen of urine is immediately examined for glucose and diacetic acid. If the specimen contains glucose and a definite diacetic acid reaction, procure a specimen of blood for glucose and carbon dioxide estimation, these analyses being done in the laboratory during operation, and then immediately administer ten or more units of insulin, depending upon the glycosuria and the urinary evidences of acidosis before operation.

Routine diabetic preparation should be instituted a day or two before. Acidosis and blood sugar estimations prior to first meal after admission are made, and if acidosis and hyperglycemia are present, administer insulin in proper amounts, estimating insulin effect by blood chemistry within three hours. If the case is a severe one, repeat blood chemistry during the night and administer additional insulin if indicated. Give enemas. Diabetics should not be purged. If not a gastric case, permit patient to take carbohydrates in liquid form and drink water up to one hour prior to operation. Insulin in proper doses immediately before operation if glycosuria or hyperglycemia are present. There is no ideal anesthetic for diabetics. If spinal or local anesthesia

can be used these should have preference, then nitrous oxide-oxygen, ether, and lastly chloroform. Liquids immediately after operation, either by proctoclysis, hypodermoclysis, or intravenously, according to the chemical severity of the case. Patient should receive 1000 c.c. of liquids every six hours. Subsequent insulin dosage is regulated by the chemical data of the patient, and if this shows marked change from normal prior to operation, give twenty units of insulin immediately after operation is completed. The danger time for post-operative diabetics is from three to five hours after the completion of the operation. Blood chemistry studies should be made at this time even if the patient is conscious.

The postoperative treatment of diabetics requiring surgery differs materially from the after operation treatment of many surgeons. The authors give carbohydrates and liquids within two or three hours after operation is completed. If oral administration is contraindicated, give glucose intravenously and liquids parenterally, for the only way to prevent post-operative acidosis is by administering carbohydrates, liquids, and occasionally insulin.

BLOOD AND LYMPH GLANDS

Results of Radiation Therapy in Leucemia and Lymphogranuloma.—P. F. Schreiner and Walter L. Mattick (*Journal of Cancer Research,* December, 1924) report their results with radiation therapy in twenty-five cases of leucemia and forty-six case of lymphogranuloma. They found that radiation therapy is empirical, like the medical treatment of these diseases, but tends to induce remissions with least inconvenience to the patient. Medical treatment should be used wherever indicated in conjunction with radiation therapy. Radiation therapy was given in two acute cases with temporary improvement. An optimal dosage is still desired for both diseases. The authors have seen no cures of leucemias or Hodgkin's disease by this form of therapy, but marvelous amelioration of symptoms and remissions have resulted which, however, were not permanent.

Volume and Composition of the Blood in Addison's Disease.—George E. Brown and Grace M. Roth (*American Journal of the Medical Sciences,* January, 1925) say that of seventeen cases of Addison's disease observed at the Mayo Clinic, definite anemia was present in only one (six per cent.). A mild or questionable anemia was found in four cases (twenty-three per cent.). In three of five cases the cell volume index was decreased, and in three the saturation index was increased, indicating small erythrocytes with high hemoglobin content. A relatively high lymphocytosis was present in the majority of cases. According to the dye method, normal circulating blood and plasma volumes, or simple normovolemias were found in all but one case. Decreased percentages of water and of blood and plasma were observed in one case during the period of acute suprarenal insufficiency. Anemia, when associated with Addison's disease, is apparently not due to a dilution, or an increase in total blood volume, since large blood volumes did not exist in the presence of anemia. Anemia was not masked by contraction of volume, since normovolemia existed in all cases in which hemoglobin values were normal. Repeated volume determinations in three cases revealed in two marked fluctuations in cell and plasma volumes. The volume fluctuation masked only in a minor degree the percentage hemoglobin changes, since the normal cell plasma volume ratios were closely maintained.

On the Alleged Power of Bacteria to Form Bile Pigment from Hemoglobin.—Arnold R. Rich and John H. Bumstead (*Bulletin of the Johns Hopkins Hospital,* May, 1925) found that whole blood, laked blood, and solutions of hemoglobin subjected to the action of Type I pneumococcus, staphylococcus aureus, streptococcus viridans, and air bacteria showed no formation of bilirubin in amounts detectable by the van den Bergh test, the Gmelin test, or by extraction with warm chloroform. However, when these solutions were layered with nitrous acid in the Gmelin test, a distinct greenish ring slowly made its appearance in each case; but the play or colors characteristic of bilirubin, although watched for closely, was never seen. No attempt was made to determine upon what substance the appearance of the green ring depends, but in view of the negative van den Bergh test, the chloroform extraction test, and the failure of the other characteristic colors of the Gmelin test to appear, it is apparent that the substance causing the green rings was not bilirubin.

Pernicious Anemia in Its Relationship to Sprue.—Edward Jenner Wood (*American Journal of the Medical Sciences,* January, 1925) says that the close similarity of pernicious anemia and sprue suggests the possibility of the two being types of the same condition. Equally as readily in pernicious anemia as in sprue, the Monilia psilosis can be recovered from the feces, the gastric contents and the gums when pyorrhea exists. The study of the yeast is made extremely simple by the employment of a modification of Sabouraud's medium. By feeding guineapigs with the Monilia psilosis a hemolytic anemia was produced. There were also produced changes in the liver and bone marrow which were suggestive of the action of a hemolytic poison. A filtrate of the Monilia psilosis in dextrose water injected intravenously into rabbits caused blood changes apparently hemolytic in nature.

Incubational Changes in the Red Cell Count in Inoculated Malaria.—Adrianus Piper and Beth Dill Russell (*British Medical Journal,* October 4, 1924) show that a subcutaneous injection of from 0.5 to 10 c.c. of blood containing benign malarial parasites is quickly followed by a rise in the red cell count amounting to somewhere between ten and thirty per cent. This rise lasts several days, with minor daily variations, and is followed by a fall, which constitutes the malaria anemia. As an injection of malarial blood cannot very well lengthen the life of red blood cells, the rise can only be explained as an increase in production of red blood cells. Normal blood has no such effect. An injection of malarial blood is a direct stimulus for the red bone marrow toward increased activity. This stimulus might be applied for therapeutical purposes (forms of anemia, especially chlorosis). The outbreak of fever can always be prevented by an injection of neosalvarsan as soon as the increase in red cells is well established.

Chloride Content of the Blood in Pernicious Anemia.—Russell L. Haden (*Journal of Laboratory and Clinical Medicine,* April, 1925) reports the chloride determinations in thirty cases of pernicious anemia and twenty cases of secondary anemia. The whole blood chlorides are usually higher in blood with a low cell volume in both primary and secondary anemia. The plasma chlorides remain about normal regardless of the cell volume A few cases of pernicious anemia show a low chloride content. No patients with secondary anemia had low chlorides. There is no relation of the chloride level of the blood to the free hydrochloric acid of the gastric juice or to the volume index of the corpuscles. The total store of chlorides in patients with very low cell volumes is higher than normal since the blood volume shows little variation from normal and the plasma chloride content is higher than whole blood. These results give no positive evidence of a disturbance of chloride metabolism in pernicious anemia.

Inorganic Alterations of the Lymph in Canine Anaphylactic Shock.—W. F. Petersen and T. P. Hughes (*Journal of Biological Chemistry,* March, 1925) conclude from their studies on dogs in anaphylactic shock that their lymph shows an immediate increase in volume; an immediate increase in calcium; an increase in amino nitrogen; an immediate increase in magnesium; a decrease in the sodium level; and also in the potassium level; a progressive increase in phosphate, depending on the severity of the shock; and a constant level in chloride content. Preliminary stimulation of the sympathetic system increases the effect of the shock.

Observations on Blood Lactic Acid After Insulin.—Charles H. Best and J. H. Ridout (*Journal of Biological Chemistry,* March, 1925) estimated sugar and lactic acid in the blood of dogs before insulin and at varying intervals from 15 minutes to 5 hours after its administration. The results show that lactic acid of normal or diabetic dogs' blood does not significantly increase during insulin hypoglycemia when this condition is uncomplicated by extreme asthenia or marked hyperirritability.

The Comparative Value of Blood Transfusion and Blood Tonics in Secondary Anemias.—Martin Lewis Janes (*American Journal of the Medical Sciences,* April, 1925) says that persons suffering from secondary anemia due to acute or chronic disease regenerate hemoglobin and red blood cells more rapidly, more effectively, more completely and within a shorter period of time by periodic blood transfusion than those receiving inorganic iron or arsenic preparations. Iron and arsenic preparations exercise practically no beneficial effect in correcting secondary anemias.

Medicolegal Notes.

FREEZING OF HAND HELD NOT COMPENSABLE UNDER WORKMEN'S COMPENSATION ACT

The Michigan Supreme Court holds, Hargrove v. Arnold Const. Co., 229 Mich. 678, 202 N. W. 918, that a brick mason tender, who while at work froze his hand so that amputation of part of the middle finger was necessary, did not suffer an "accident" within the Workmen's Compensation Act.

The same court holds, Sherman v. Flint Spring Water Ice Co., 229 Mich. 648, 202 N. W. 936, that where an employee harvesting ice fell and threw his hand into the water far enough to wet his mitten, which he afterwards wore for two hours when thermometer was seventeen degrees below zero, the subsequent freezing of his hand was not compensable under the act.

CONSTRUCTION OF PRIVILEGED COMMUNICATIONS STATUTE

The Wisconsin Supreme Court holds, In re Williams' Estate, 202 N. W. 314, that the statute, St. 1923, section 4075, prohibiting physicians from disclosing information acquired while attending patients professionally, should be liberally construed to effect its purpose, but not so strictly as to exclude the opinion of a physician as to the mental condition of a person, based upon observation alone, during a given period, because the physician may have rendered professional service for that person at an earlier or later time.

UNLICENSED PRACTITIONER CANNOT RECOVER FOR SERVICES

The Iowa Supreme Court holds, Lyon v. Leet, 202, N. W. 881, that, under the general and uniform holding of the courts that one who publicly professes to cure or heal, or holds himself out as a physician without a license to practise medicine as such, cannot recover compensation for his services rendered in such capacity, a note given to a chiropractor who publicly professed to heal or cure without a license in violation of Iowa Code 1897, section 2579, for services, prior to the enactment of Acts 39th Gen. Assembly, c. 7, regulating the practice of chiropratic, was void in the hands of the original payee thereof.

MEDICAL EXPERT'S OPINION AS TO POSITION OF VICTIM FROM COURSE OF BULLETS HELD ADMISSIBLE

In a murder prosecution the medical examiner testified to facts revealed at an autopsy performed by him on the deceased's body. It being the contention of the prosecution that the shots which killed deceased were fired at him while he was seated at a table, the medical examiner was permitted to testify that the course of the bullets through the body of the victim was such that he was sitting and could not have been standing on a level with the person who fired the shots, and that the latter must have been at some elevation above the person shot. He also was permitted to testify that the deceased could not have held a gun in his hand after the bullets entered his body. The Massachusetts Supreme Judicial Court held, Commonwealth v. Festo, 146, N. E. 700, that there was no error in admitting this testimony. "It related to matters outside the range of common experience. It pertained to an exact knowledge of the anatomy and the vital organs of a human body and the course of projectiles through it. It cannot be presumed that a jury would not be aided by the technical learning of a medical examiner of experience on such a subject."

MEDICAL OPINION NOT BASED WHOLLY ON EXAMINATION HELD INADMISSIBLE

At a hearing before the Illinois Industrial Commission under the Workmens' Compensation Act a physician testified that in his opinion the claimant's condition, claimed to be due to an injury to his back, was due to trauma. He also stated that he based this opinion partly upon the history of the case. The Illinois Supreme Court, Lehigh Stone Co. v. Industrial Commission, 315 Ill. 431, 146 N. E. 533, holds that this rendered his opinion incompetent. Expert witnesses are not permitted to give opinions based upon subjective symptoms. He did not treat the claimant, but examined him for the purpose of testifying. His opinion was not based wholly on his examination, and it was therefore held to be incompetent.

HOSPITAL NOT LIABLE FOR NEGLIGENCE OF ORDERLY

The New York Court of Appeals holds, Phillips v. Buffalo General Hospital, 239 N. Y. 188, affirming 207 App. Div. 640, that the complaint was properly dismissed in an action by a paying patient against a charitable hospital for injuries sustained through the negligence of an orderly who placed a hot water bottle against the plaintiff's body while she was in bed, unconscious after an operation. The court said that one who is brought unconscious to a charitable hospital as a patient does not assume the risk of malpractice on the part of the hospital; one who pays a substantial sum for room and care is not in any true sense, according to common speech, the recipient of charity and only by an hyperable may a hospital which collects $24.50 a week for board, lodging and care in a semiprivate ward be classed with the Good Samaritan, but it unquestionably has been stated to be the law of the state of New York that the beneficiary of a charitable trust may not hold the corporation liable for the neglect of its servants (Hordern v. Salvation Army, 199 N. Y. 233). The orderly, so far as he engaged in nursing, under the authority of the hospital, was supposed, like other nurses, to act on his own responsibility. If his act was unauthorized by the hospital, the rule of *respondent superior* did not apply. In neither case, as between hospital and patient, was his negligence the hospital's wrongful act.

PROMULGATION OF STATE BOARD OF HEALTH RULES MUST BE SHOWN IN PROSECUTION

In a prosecution for obstructing a health officer and refusing to allow a coyote which had bitten a person to be tested for rabies, the Oklahoma Supreme Court holds, Shilkett v. State, 232 Pac. 127, that within reasonable bounds the Legislature may confer regulative powers upon the state board of health and give the board authority to adopt rules and regulations having the force and effect of law. But where the public health statutes make no specific provision for the suppression or control of rabies and there are no averments in the information that the board promulgated any rules on that subject, the courts will not assume that such rules were promulgated.

REPORTS OF EXAMINING PHYSICIANS AS EVIDENCE

The California Legislature having amended the Workmen's Compensation Act to permit the receipt of reports of examining physicians as evidence by the Commission, it is held, Hart v. Industrial Accident Commission, 235 Pac. 748, that the weight and credibility to be given thereto is for the Commission and not for the court.

It is also held that the Commission is "justified in acting upon the report of an examining physician rather than upon theories, or suppositions or statements found in books, because the writer of the report undoubtedly knew at the time of making the same that he was subject to the call of the Commission and could be specifically and thoroughly interrogated as to any matter or statements contained therein."

The Constitutional Effect of Prolonged Intestinal Toxemia

WILLIAM SEAMAN BAINBRIDGE, A.M., M.D., Sc.D.
New York

There may seem some necessity to apologize for again introducing a subject about which such a vast store of literature has been produced. However, the present writer thinks with John Abernethy "that if we believe propositions to be true, or perceive truths to be important, however unimportant they may at the time appear, and if we neglect to draw inferences from them, we fail in essential duties." My object in presenting this paper is to show how prolonged intestinal toxemia often may be the unsuspected underlying cause of diffuse autointoxication, and how, frequently, the most disseminated toxicosis may be controlled by the medical, mechanical, or surgical correction of morbid intestinal conditions.

There can be no point in stressing the part which absorption from diseased tonsils, teeth, sinuses, prostates, uteri, tubes, and gallbladders may play in autointoxication, nor for enumerating the many pathological conditions, both mental and physical, which may be traced to these sources of infection. Overwhelming evidence of such selfpoisoning may be found on every hand!

Obviously, the first aim in the elimination of any toxic state is to determine the original and exact source of the focal infection—a particularly difficult matter when the source is centred in the intestinal canal, where the shifting and distention of the intestinal coils cause a constant element of uncertainty to be present even in the röntgen interpretation of abdominal conditions. However, x ray and fluoroscopic examinations, carefully executed and properly interpreted, combined with a skillful and thorough clinical diagnosis, should prove accurate methods of demonstrating any important defect of the intestinal tract.

Without doubt, medical science is agreed that there are many patients today who exhibit areas of local stagnation in the bowel. That these areas are due, in many cases, to mechanical causes—adventitious bands which form about certain sites of the gastrointestinal tract, causing kinking of the gut at points of fixation, is scarcely a fact likely to be disputed, though there may be some disagreement as to the etiology of these bands. They may prove of congenital or inflammatory origin; or, the evolutionary theory, by which Lane has interpreted their existence, may account for the greater proportion. Whatever their etiology, the result of their formation may cause an unequal support in different portions of the canal, in consequence of which obstructions, as a result of a kinking of the gut, occur and a slowing of the passage of the contents of the intestines is the result. The degree of obstruction will depend upon the extent of the kinking of the gut, the number and type of bands and the length of time the intestinal conditions have existed. The treatment, whether medical or surgical, must depend upon the amount of stasis present.

A point of delay in the passage of the contents of the intestinal canal frequently provides an ideal site for the absorption of toxins, although, as we know, the absorptive powers of the canal vary at different sites. Many interesting scientific experiments have been undertaken to establish the causes of symptoms and of death in intestinal obstruction. These experiments have seemed to prove that in such obstruction death is not due to the loss of the mechanical function in the obstructed loop, but rather to the toxic content of the blocked portion of the canal. While these studies refer primarily to acute intestinal obstruction, there seems little reason to doubt that the toxemia produced by an acute condition and one produced by a chronic condition differ largely in the severity and rapidity of the climax. The toxicity in acute obstruction frequently will cause death within a few days, while that of chronic intestinal poisoning may produce symptoms over a period of years, particularly in autotoxic subjects who have acquired a certain amount of immunity which saves them, sometimes for years, from the serious sequelæ of their condition. The effect on the constitution of prolonged intestinal toxemia, I wish to emphasize in this paper.

The close relationship between a toxemia originating in the alimentary tract and the many apparently remote symptoms in the patient has long been recognized, though, perhaps, not duly stressed. One of the first symptoms exhibited by the autotoxic subject is the remarkable change in the skin which, in many of these cases, becomes darker and darker and progressively pigmented. On the back of the upper arm the skin may be thick and feel, in severe cases, as if it were affected by a firm, brawny edema. The skin on the forearm and hand is mottled, being bluish and yellow in patches, while the fingers may be blue or cyanotic.

Copyright, 1925, by A. R. Elliott Publishing Company.

Intestinal toxemia is common among the causative factors of socalled functional heart disease. People who suffer from socalled indigestion of long standing very often develop, in time, structural changes in the heart muscle. Sir James Mackenzie frequently referred in his writings to "poisoned hearts." He described these toxic heart patients as exhibiting other phenomena indicative of toxic poisoning—discoloration of the skin; general exhaustion with collapse and long periods of unconsciousness. Mackenzie reported a case of a woman who suffered from a Bacillus coli infection for some years. "Her heart muscle had been affected to such an extent that even the most elaborate methods of treatment for the heart condition had been without result. The prognosis was bad. Finally, medical treatment for the intestinal toxemia was instituted and, after eighteen months of such treatment, a complete recovery was secured, in spite of the severity of the cardiac impairment."

Dr. F. A. Craig recently reported "that in nine thousand cases of intestinal toxemia which he treated, one third of the patients had had sanatorium experiences for socalled neurasthenia." He adds "that in many of these cases there were very clear evidences of toxic poisoning—sluggishness of the mentality, loss of concentration, memory and coordination." The mental depression and depreciation associated with prolonged intestinal toxemia are, in many instances, of severe type. Patients so handicapped are unable to concentrate. They are subject to attacks of faintness, vertigo, neuralgia and headache due to the large excess of toxic material in the circulation.

Sir Arbuthnot Lane reports the case of a medical man who for years had been so drowsy, much of the time, as to appear to be under the influence of a narcotic. In time, the condition became so intolerable that it was impossible for the physician to continue in practice. Finally, he was operated upon and, following the surgical correction of the intestinal stasis, the mental condition cleared and the patient was enabled to resume his professional life.

In an earlier paper, I recorded a series of cases of abnormal mammary changes apparently caused by autointoxication. In many of these breasts a condensation or lobular induration of the upper, outer quadrant, develops usually along the edge of the large pectoral muscle, and where the dependent breast drags on the upper axillary margin. In some cases there is an abnormal discharge from the nipple, in conjunction with the condition described above. Such terms as toxic breasts, lumpy breasts, or stasis breasts are applicable to mammary changes of these types.

The two following cases are reported to illustrate 1, the result upon an abnormal breast condition of the surgical correction of the intestinal stasis, and 2, the return to normal of the mammæ when a coexistent intestinal toxemia was relieved by therapeutic measures.

Case I.—A.B.; twenty-five years of age; widow. In March, 1915, this patient had an attack of pain in the right iliac fossa. There were several recurrences of the pain which was so severe that it was necessary for the patient's physician to prescribe morphine.

In August, 1915, a lump developed in the left breast, accompanied by a bloody discharge from the nipple. A diagnosis of cancer was made by two physicians, and a radical amputation of the breast advised.

During February, 1916, the patient consulted me. On examination, I found distinct tenderness of the right iliac fossa, much abdominal gas, and a socalled lumpy condition in the upper quadrant of the left breast which on deep pressure exuded a bloody serum from the nipple. I advised that the breast be kept under careful surveillance, and that the abdominal conditions be corrected surgically.

Abdominal section was performed March 11, 1916. The cecum was found to be large and pendulous; the terminal ileum dilated; there was an incompetent ileocecal valve, and many abdominal bands and adhesions. These conditions were corrected.

Convalescence was uneventful. A short time after the operation, the lumpy condition of the breast and the bloody discharge disappeared. In May, 1924, the patient was in excellent physical condition, and upon examining the breast I found it normal.

In this case a definite pathology of the breast tissue was eliminated by the timely surgical correction of the factors responsible for the intestinal toxemia.

Case II.—I. M.; twenty-five years of age; female; single. This patient consulted me in May, 1919, for a lumpy condition of the right breast. On examination I found general enteroptosis; masses of feces in the lower colon; considerable gas in the transverse and ascending colons; a floating kidney and a lobulated condition in the upper, outer quadrant of the right breast. Tonics, an uplifting corset, laxatives, special abdominal exercises, and a general hygienic régime were prescribed. After following these therapeutic measures for one year the patient reported that the breast lumps had completely disappeared. By careful attention to the intestinal tract the patient has prevented any recurrence of the abnormal condition, and the breast is normal today, six years afterward.

Not only the breast, but the thyroid and other glandular tissues are dependent upon the type of the blood supply for their nutrition. The thyroid gland in particular must be supplied with the proper material in order to secrete and thus help maintain the proper endocrine balance of the individual.

Leonard Williams, in writing of thyroiditis, says: "There are hundreds of people who have a daily evacuation of the bowels but who are, nevertheless, walking septic tanks. These tanks are terrible depressors of the thyroid and unless you empty and disinfect them, your correct diagnosis of thyroid inadequacy, and its logical thyroid therapy, will avail you nothing."

The weight of evidence today tends to prove that alimentary toxemia is the basic cause of numbers of goitres, and that many goitres of this type diminish or disappear as a result of medical or surgical measures which have the effect of draining the intestines.

McCarrison (Robert), by the oral administration of fecal bacteria to animals, is able to produce goitre, cretinism and parathyroid disease in them. He has treated many goitres with vaccines prepared from organisms known to inhabit the intestines, and reports considerable success from such methods.

FIG. 1 FIG. 2 FIG. 3

FIG. 1.—A, large cecal diverticulum; B, socalled Jackson's membrane; C, kinked and underhung appendix; D, ileopelvic band; E, ileum held up by a retractor, it is distended by the backward flow of intestinal content from the large bowel.

FIG. 2.—A, band constricting large bowel; B, appendix; C, distended diverticulated cecum; D, dilated duodenum from backward pressure of bands.

FIG. 3.—A, socalled Jackson's membrane; B, appendix; C, diverticulated cecum; D, dilated ileum.

I do not wish to imply that all types of goitre can be cured by the measures, either medical or surgical, which restore the function of the intestinal canal. There are, however, cases of thyroidism which clear up completely when the toxic elements of the system are removed—as the atrophic gland, with small isthmus, which may increase in size and function when the toxemia is relieved, or the hypertrophic gland which also may resume normal functioning when the auto intoxication is eliminated. As early as 1779, the relation between goitre and a static condition of the intestines was outlined by Wilmer, a surgeon of Coventry, England, who, in an old and interesting volume of surgery, cited two cases of bronchocele (goitre) which were cured by "certain measures." In one case the prescription called for "a medicine composed of millepedes, burnt spunge and cinnabar of antimony." The patient was to be "purged at intervals with mercurial cathartic pills." Probably the "purging at intervals" had a more vital bearing on the cure of the bronchocele "in forty days" than was evident to the author of the illuminating old volume.

In many cases of toxic goitre, the medical or surgical treatment of the intestinal condition will relieve the abnormal stimulation of the thyroid gland. There are, of course, many patients who are so thoroughly poisoned with thyroid toxins that correction of the intestinal condition *alone* is useless and in these cases the necessity for thyroidectomy is evident.

The two cases herewith reported illustrate most clearly that the relief of intestinal stasis by surgical means may largely correct a persistently morbid condition of the thyroid, and restore the normal functioning power of the gland.

CASE III.—B. N.; thirty-five years of age; female; married. This patient consulted me February, 1917. She was suffering from pain in the epigastrium, and continued vomiting. There was tenderness in the

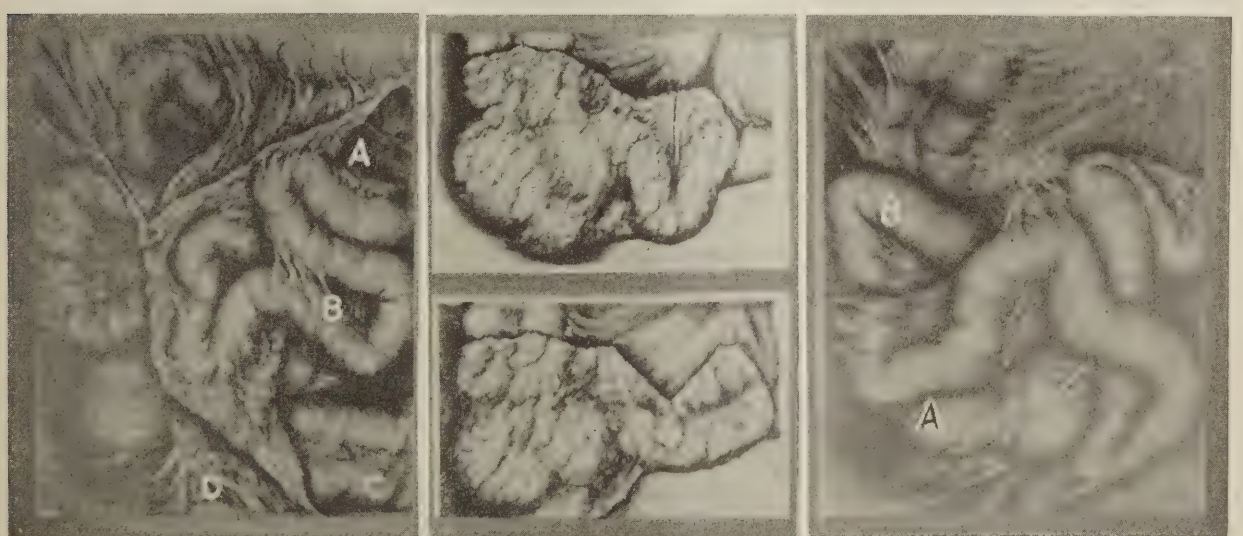

FIG. 4.—A, omental adhesions; B, adhesions between cells of small bowel; C, large bowel.

FIG. 5.—Omental grafts placed over raw surfaces of intestine.

FIG. 6.—A, cecum; B, loop of small bowel over large gut, adherent to lateral wall.

right iliac fossa and over the gallbladder. Her weight was 203 pounds. Her breasts were large and dependent. The thyroid gland was atrophic. X ray photographs showed esophageal diverticulum, and intestinal bands and adhesions constricting many points.

Laparotomy was performed May, 1917. There was marked constriction of the ascending colon by a very tight band across the gut. The adhesions which covered many other points in the intestines and a chronically inflamed appendix were removed.

The autointoxication had been present for years and the thyroid gland had become atrophic to such an extent that it was necessary to institute thyroid therapy.

Since the operation the patient no longer suffers with the abdominal pain or with the vomiting. She has lost fifteen pounds. As a result of the elimination of the intestinal toxemia, the thyroid gland is functioning in a more satisfactory manner but the prolonged autointoxication has damaged the gland to such an extent that some thyroid therapy, although less than formerly, is necessary in order that the patient may lead a comfortable and normal existence.

Case IV.—A. S.; twenty-four years of age; female; single. This patient consulted me in May, 1916. She had a large goitre; there was pulsation in the neck, and the eyes were prominent. The patient complained of soreness and pain over the appendicular region.

X ray examination showed intestinal adhesions and bands, and operation was performed June 10, 1916. The head of the colon, with very short mesentery, and terminal ileum were found to be apparently congenitally retropoised and attached to the posterior wall with a broad band. The appendix was subacutely inflamed and filled with material. There was accentuation of the last kink of the pelvic colon. These conditions were corrected and the patient's recovery was uneventful.

Four months after the operation there were no longer any abdominal symptoms and the goitre had completely disappeared. Five years later the patient reported that she was in excellent health.

The cases herein reported will bear out the premise that autointoxication, as a result of intestinal stasis, may be the basic factor in many abnormal mental and physical conditions. Premature senility of the organs and the impairment of the functions of the tissues are, perhaps, the most evident results of prolonged intestinal toxemia.

There are many cases of intestinal stasis, with resultant autointoxication, in which the static condition of the intestines may be obviated by early therapeutic measures, as I have repeatedly pointed out in previous papers. These are mild cases of stasis, some of congenital origin, which respond to purely preventive action. In an interesting paper purely preventive action. In an interesting paper (1) Dr. E. M. Mosher emphasizes "skeletal variations" stasis and states "that in the measurement of one hundred enteroptosis cases she found, without a single exception, the sternum short and the sternopubic diameter long, whereas in women in whom no enteroptosis was manifest, a long sternum and comparatively short sternopubic diameter was the rule." Dr. Mosher adds "that marked disproportion between the sternal length and the length of the abdomen upon its median line means a weak abdominal wall. The congenitally short sternum cannot be lengthened, nor the sternopubic line shortened, but the costal angle can be widened and the abdominal wall strengthened, in many cases, by well directed exercises." Dr. Mosher suggests "that physicians should carefully classify patients with reference to this anatomical defect and instruct mothers, teachers and physical educators regarding the importance of beginning with the child such developmental exercises as will tend to correct this skeletal defect." Physiotherapy, with special abdominal exercises, is often of great benefit in many of the earlier cases of intestinal stasis.

In all beginning types of stasis, with enteroptosis, a properly fitted and adjusted abdominal belt must be worn. This should be applied constantly to correct the tendency of the abdominal viscera to downward displacement—the result of civilized man's assumption of an upright posture and a primary cause of the change in the mechanical relations of the alimentary tract—the theories of which I have described in detail in an earlier paper (Bibliography 7). The belt should be retained until Nature has restored the tone of the abdominal supports and offset the visceroptosis.

Patients with autointoxication require more fresh air than the normal person—so that the increased toxic products of the system may be oxidized into a form which can be easily eliminated. Plentiful hydration is also an asset. Since the aim in all intestinal toxemia is to reduce the gastrointestinal fermentation, the diet should be antiputrefactive as far as possible and sufficiently laxative to produce a satisfactory emptying of the bowel, preferably night and morning. Too much emphasis cannnot be placed on these daily evacuations.

Ochsner (E. H.), in treating patients suffering from chronic fatigue intoxication says, "that some of the most severely afflicted can be saved only if they are given one ounce of castor oil every evening, in order that the results of the faulty digestion may be removed from the intestines daily and the fatigue material which may have found its way into the gastrointestinal canal be eliminated before it is reabsorbed." My own experience has proved that liquid paraffin, intestinal antiseptics and high colonic irrigations are among the most efficacious methods of overcoming the absorption of toxins from the intestinal canal, in early cases of stasis. Kaolin and belladonna are adjuncts suggested recently by some writers who state "that these drugs control the spasm in inflamed conditions of the bowel and help to reduce the infection of the food supply."

In the midgroup of stasis are placed those cases which have progressed to the point where preventive measures—medical measures—are inefficient. These require surgical procedure of the first degree In many of these conditions of stasis it is possible to repair the drainage system by severing bands, straightening kinks and angles and replacing the hollow organs. The bands should always be cut transversely and sewed longitudinally, in order to give action to the constricted part of the gut, and,

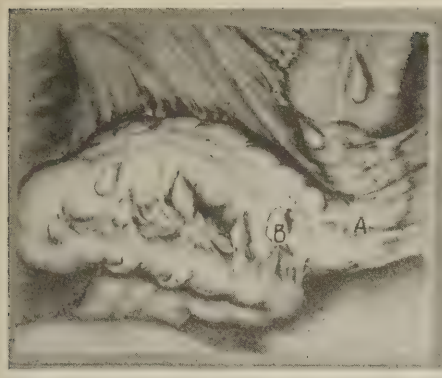

FIG. 7.—A, accentuated last kink; B, adhesions.

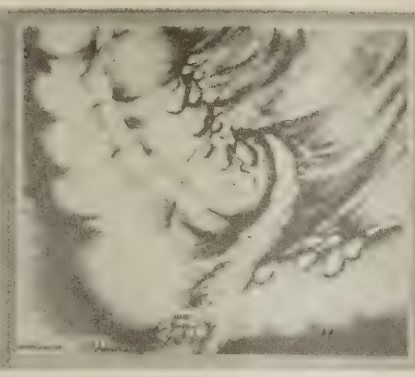

FIG. 8.—A, cecum; B, terminal ileum adherent to caput coli.

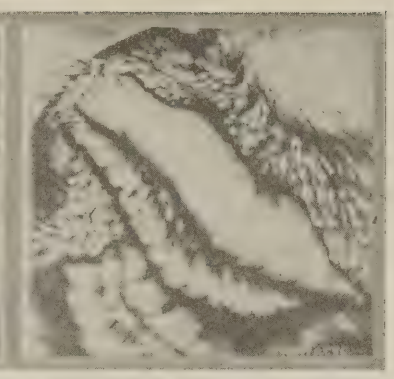

FIG. 9.—Adhesions in right upper quadrant, involving stomach, liver, and large bowel.

since the appendix often plays a large part in the kinking of the ileum and the misplacing of the cecum, its removal will prove an added advantage. The great majority of stasis cases demanding any surgery may be placed in this midgroup class and, by careful plastic surgery of the intestinal canal, the patients may be saved the necessity of more radical operative procedure at a future date.

The following case reports illustrate the type of cases which come under the head of gastroenterological plastic surgery—the midgroup stasis—and something of the surgical technic which I employ.

CASE V.—J. B.; thirty-seven years of age; married; three children. This patient consulted me February 15, 1917, for pain in the epigastrium; excessive gas; a feeling of constant distention, and the loss of thirty pounds in weight in one year. There were many headaches and marked depression. Clinical and x ray examinations indicated that there were a number of adhesions causing intestinal stasis.

Operation was performed March 16, 1917. On opening the abdomen the great omentum was found firmly adherent to the abdominal wall along the line of an old incision through which the appendix had been removed some years previously. The abdominal wall, the caput coli and about two two feet of the small intestine, nearest to the ileocecal valve, were also caught in the omental adhesion. When the omentum was released from these attachments, the last two feet of the small intestine was found angulated upon itself, twisted upon its long axis and kinked on its short axis; it was difficult to believe that anything could pass through a gut so angulated. The butt end of the cecum was found adherent to the flank with a marked ileopelvic band running down into the true pelvis. This was bisected transversely and sutured longitudinally and the small gut brought into position. A loop of the redundant sigmoid was also adherent to the cecal region and a section was grown together by an amalgamation of the appendices epiploicæ. There was a band across the duodenum from the gallbladder to the transverse colon.

All the bands were bisected and the raw surfaces turned in as far as possible. On the cecum and lower ileum some areas of raw surface had to be covered with omental grafts. The convalescence was uneventful, and in March, 1924, the patient reported that he was in excellent mental and physical condition.

FIG. 10.—A, duodenal jejunal angle markedly accentuated; B, jejunum empty; C, transverse colon.

CASE VI.—R. C.; male; forty-five years of age; single; lawyer. For sixteen years this patient had pain, off and on, in the region of the gallbladder and right shoulder. He had a great deal of indigestion; belching of gas; regurgitation of food; constipation and, at times, breathlessness. Seven years previous to consulting me he had had his appendix removed and a year later cholecystotomy performed, but the gastric symptoms had not disappeared.

On examination, I found tenderness midway between the appendical scar and the umbilicus, and on deep pressure, up under the costal arch. There was much gas in the intestines.

X ray examination showed adhesions about the descending duodenum and in the region of the gallbladder, with distinct points of kinking.

Operation was performed September 12, 1917. On opening the abdomen there was found a dense mass of adhesions in the right upper quadrant. Two and a half feet from the ileocecal valve the small gut was turned to the outer side over the ascending colon and was adherent to the posterolateral wall of the abdomen, and there were adhesions from the gallbladder to the small intestine which kinked it at an acute angle. This extremely tight band was cut transversely, the intestine released and the raw surfaces turned in. A marked ileopelvic band which bound the terminal ileum tightly over the right ureter and internal iliac vein, and a band across the hepatic flexure were severed. The liver, outlet of the stomach and duodenum were all encased in the mass of adhesions. These were all released, raw surfaces carefully sutured, and the abdomen closed. The patient had an uneventful recovery and, in the eight years since operation, has remained in excellent condition.

CASE VII.—E. A.; eleven years of age; female. This patient came under my care in June, 1916, at the suggestion of Dr. Graeme Hammond. The birth and early childhood were normal except for

chronic constipation which was present even during babyhood, when it was necessary to give the child an enema almost daily. X ray of the skull showed no abnormality. The family history is irrelevant.

In September, 1915, at ten years of age, the patient had attacks of what was apparently *petit mal* —as many as twenty a day. She was placed in a hospital where she remained for four months taking a rest cure; on a fruit and vegetable diet for eleven weeks and, later, on a milk diet for five weeks. The attacks did not abate. Dr. Hammond barred out essential epilepsy, and sent the patient to me.

On clinical examination, I found distinct tenderness over the head of the colon and appendix. The large intestine was prolapsed; the cecum was much distended and lay in the true pelvis. X ray of the intestinal tract showed "a delay in the passage of the food through the terminal ileum, the transverse colon and sigmoid. The appendix retained barium for several days. The colon plates, twenty-two, forty-seven and seventy hours after the injection of the solution showed that a large amount of the barium was retained in the colon, and dilated the cecum and ascending colon."

Operation was performed June 23, 1916. The gallbladder was distended and attached to the first portion of the duodenum by a tight band which continued down over to the transverse colon near its hepatic flexure, which was prolapsed. The stomach was dilated to an unusual degree for so young a child, the greater curvature almost to the bladder. A band, about three inches broad, ran from within an inch of the tip of the gallbladder to the vessels of the gastrohepatic omentum. There was a duodenal kink of marked degree. Just above the cecum the ascending colon was bound down tightly; the hepatic flexure was grown to the ascending colon and the sigmoid was very redundant. There was an ileopelvic band, about three inches from the ileocecal valve, which was so placed mechanically that the cecum, which had already begun to form a diverticulum, caused a degree of ileal stasis which might easily account for the ileal delay. The bands were severed; the diverticula were turned in, first being treated with iodine; the cecum was plicated, and the cecum and ascending colon were elevated, rotated outward and anchored to the posterolateral shelf. The patient left the table in good condition.

Following the operation, the nerve condition rapidly improved. The seizures of *petit mal* were reduced to a minimum and, except for a slight attack at long intervals (and these usually follow a protracted excitement or fatigue), finally disappeared. The patient has remained in excellent physical condition—a member of the high school basket ball team—and has made a brilliant record as a student both at high school and during her first year at college. She enjoys all the pursuits of the perfectly healthy girl and, on examination, August, 1925, I found her normal in every respect.

The most advanced cases of intestinal stasis are those which, because of neglect, or despite preventive treatment, have progressed to a point where plastic surgery is no longer effective and more than conservative measures are indicated. In previous papers, I have stressed again and again the importance of *early* surgical correction of intestinal stasis (cutting bands, anchoring, plicating, straightening kinks and angulations, etc.) and have emphasized particularly the necessity of corrective surgery at the site of the socalled last kink. Too little attention has been paid by surgeons to this angulation. It is this last kink which frequently attaches itself to the left ovary which, in consequence, may become cystic. The rectum, too, may become involved. In numerous cases of stasis which have come under my observation, the crux of the entire static intestinal condition was centred at this point of the canal and surgical repair of this one kink eliminated the intestinal stasis.

In my own experience, short circuiting in extreme types of stasis, where other surgical measures of lesser degree have failed, has often given most satisfactory results. I have always maintained that except in the rare instance, or where malignancy may have developed, partial or total colectomy is an unnecessarily radical operation. Recently, several operative measures have been proposed as substitutes for these more extreme surgical procedures. George E. Waugh (2) suggests an operation which he calls "fixation of mobile ascending colon." Roland Hazen (3) describes his operation "replacement and retention of the colon by fusion." Colonic exclusion is a surgical procedure suggested by Herbert J. Paterson (4). Paterson states "that in colonic exclusion nothing is removed; it is, therefore, less severe than total excision of the colon; the mortality rate is lower, and there are no tags or raw surfaces left behind to lead to intestinal obstruction." I have been fortunate in having had the opportunity to observe the technic of Paterson, Waugh and Hazen, in their own operating rooms, and to see also some of the excellent postoperative results secured by these surgeons. I believe, therefore, that before resorting to any of the more radical surgical measures these substitute surgical procedures, or any others of equal practical value, should be given the most thorough investigation and thoughtful consideration.

In ileocolostomy the abdomen is opened and the lowest point of obstruction located. The ileum is divided slightly obliquely, encroaching upon the convexity; the distal end is invaginated by a purse string suture, and the proximal end is implanted into the lowest accessible portion of the pelvic colon (an end to side junction; or a lateral or oblique). A full sized esophageal tube may be introduced through the anus, up through this anastomotic juncture, its passage being facilitated by injecting paraffin into the tube by means of a Higginson syringe. The tube is passed through the opening in the colon and for about twelve inches along the ileum. It is secured in the anal region in the male and to the back of the vulva in the female—and the short circuit is complete. The tube remains for three to seven days.

The following case report illustrates the type of intestinal stasis, which, necessarily, is placed in this group, and the operative procedure employed to correct the mechanical defects of the intestinal canal:

Case VIII.—C. Y.; twenty years of age; female; single. At thirteen years the patient began to have convulsions at intervals of two or three months. Simultaneously with the first convulsion there occurred an attack of constipation which amounted al-

most to obstipation—the bowels could not be moved except with an enema. The convulsions and attacks of constipation continued, and, after consulting a dozen physicians (and having an x ray of the skull, which proved normal), it was decided advisable to do an exploratory laparotomy.

Operation was performed by me June 14, 1916. On opening the abdomen there was found a marked accentuation of the last kink and also a redundant sigmoid. The cecum was dilated and partially prolapsed. A Y shaped band extended from the lateral wall of the abdomen, its two prongs reaching across the ascending colon at about its middle point and almost completely obstructing the gut. From this band downward toward the butt of the cecum the gut was dilated; above the band it was collapsed. The ileocecal valve was incompetent, with great dilatation of the terminal ileum. There were numbers of pericolic bands across the ascending colon but the main support of the gut was the Y shaped band extending across it to the mesial line. There was a marked duodenojejunal kink with bands underneath the transverse mesocolon extending well up toward the free margin of the attachment of the transverse colon. When these bands were cut it was clearly seen by all those present that the small intestine below the band became greatly distended. The appendix was removed and the duodenojejunal kink corrected. A short circuit was performed in the usual way, care being taken to insert below the last kink. The patient's convalescence was prolonged because of the nerve element which entered into the case but she recovered and there were no longer attacks of obstipation. The convulsive seizures are now of very rare occurrence and light in character. The accompanying photographs will demonstrate the intestinal conditions revealed at the operation.

In these various types of stasis (the beginning cases, the midgroup and the advanced), the treatment must be modified according to the individual. In many, the simpler surgical procedures will prove effectual to remove the intestinal stasis, and, thus having eliminated the causative factor, the autointoxication, with the resultant morbid conditions of the system, will disappear. The disastrous possibilities which may be the outcome of permitting these conditions of intestinal stasis—these sites of mechanical irritation, exposed to contact and strain—to remain uncorrected, can only be surmised. This much we do know of malignancy today, that cancer frequently develops at the site of prolonged chronic irritation. Sir Arbuthnot Lane writes "that as a result of his observations, which have extended over many years, he is exceedingly impressed by the sequence of cancer and intestinal stasis."

In closing, I wish to repeat that herein are presented no new principles in medicine. My chief aim in contributing this paper today is, 1, to reemphasize the vast importance of toxic absorption from the intestinal canal as the factor mainly responsible for many widely diffused and apparently unrelated morbid conditions of the body; 2, to suggest the therapeutic and surgical measures through which the intestinal stasis which produces this autointoxication may be eliminated, and 3, to offer these case reports in evidence that as soon as the prolonged intestinal toxemia is relieved, often the impaired organs and tissues resume their normal functioning powers and a cure is effected!

Tumors of the Fingers

With Report of Cases

MAX THOREK, M.D.
Chicago

Textbooks give little or no space to the description and discussion of tumors of the fingers, probably on account of the comparative infrequency of the occurrence of such tumors. In 1911, Mueller (1) reported that among 19,000 patients of all kinds treated at the Berlin Polyclinic, there were only eleven cases of finger tumors. Among those which do occur chondromata and sarcoma are the most frequent. Pure fibromata are rare, only a few cases being reported in literature, although there are many cases of mixed fibrous tumors.

I recently operated in two cases of fibroma of the right index finger, the particulars of which follow:

Case I.—G. E. F., male, white, aged fifty-three years, printer, entered the hospital on May 14, 1924. He had gonorrhea thirty-one years ago; was operated on three years ago for an affection of the foot, said to have been caused by wearing black stockings; he had had some dyspepsia. He came to the hospital on account of the tumor on the right index finger. This growth had first been noticed by patient about two years ago. It had grown very slowly, and until recently had caused neither pain nor inconvenience, but of late it had been more rapid, causing some limitation of motion and some inconvenience by its presence. No history of traumatism nor any other cause which might account for the appearance of the tumor could be elicited.

Examination showed a tumor on the basal phalanx of the right index finger, the skin over which was discolored and ulcerous, the discoloration extending to the dorsal aspect of the hand. The history and general appearance of the tumor, with a tendency to ulceration, suggesting malignancy, it was deemed best to excise the mass completely so that its exact

nature might be studied microscopically. This was done (Fig. 1). The patient made a speedy recovery, leaving the hospital in good condition a few days after the operative procedure.

Description of excised tumor.—Macroscopically the tumor when removed presented the following features (Fig. 2):

It was a hard mass, somewhat nodular and smooth

Fig. 1.—Showing location of tumor, line of incision and appearance of wound two days after operation.

in appearance and rather pale (whitish) in color. It was approximately the size of a walnut and oval in outline. On sectioning it presented a hard, glistening surface on which a few coarse fibrous bands could be seen, confirming the fibrous characteristics of the growth. It gave the sensation of fibroid tissue so frequently seen in uterine fibroids. Through the centre of the mass a small artery was noticeable, apparently the main blood supply; but on the whole the tumor was poorly vascularized. No distinct capsule or lobulation was present. Microscopically the specimen presented the typical appearance of a pure fibroma (Figs. 3 and 4). The fibres were closely packed and had an irregular distribution. The cellular elements were displaced laterally and elongated in shape. The lymph spaces of the tumor were very narrow and the blood capillaries very few.

Anatomical diagnosis.—Fibroma of basal phalanx of right index finger. An examination of the patient six months after the operation showed him free from recurrence. Motion of the finger was perfectly normal.

A similar case in which I operated disclosed microscopically the presence of sarcomatous elements, which subsequently necessitated amputation of the affected digit to prevent sarcomatous dissemination.

A fairly extensive search through the literature has revealed only a few cases of pure fibromata of the finger.

In Gurlt's (2) classical study of the occurrence and distribution of tumors, he collected statistical details regarding 16,630 neoplasms. Of these 699 were fibromata of which only two were situated on the fingers. The comparative frequency is shown by the fact that of 894 sarcoma five were on the fingers, of 136 chondromata nineteen were on the hands and fingers, and of 11,131 carcinomata only one occurred on the finger.

The earliest published case of fibroma of the finger that I can find appears to be that of Nélaton (3). This author, in 1856, reported the case of a youth fifteen years of age, from the palmar surface of whose left ring finger three such tumors were removed. The tumors had involved the fibrous tissue of the tendon sheath, although independent of it, and were histologically verified after excision.

Monod (4) reported a case of vascular fibroma of the middle finger of the left hand, in a woman fifty-three years of age. This was a mobile, nonfluctuant tumor, which had commenced thirty-three years before as a small wart. The finger was amputated, and a histological report showed that the tumor was a fibroma undergoing cavernous degeneration.

McDonnell (5) reported a case of microscopically verified pure fibroma of the left forefinger in a woman aged thirty-four years. There was no history of injury and the first appearance of the tumor was about two years previous. The tumor was lobulated and two of the lobes were ulcerous. The head of the metacarpal bone with the phalanges of the finger were removed. In regard to the origin of this tumor, the reporter states: "We can perfectly trace the origin of the tumor springing from the dorsal surface of the central phalanx. It is at the insertion of the extensor tendon and is attached at the dorsal aspect and also for some distance up the bone; but the most intimate point of attachment is where the tendon makes its closest connection with the bone. It is a fibrous tumor involving the fibres of the tendon."

Chisholm's case (6) was in a woman of twenty-seven years, who for fourteen years had suffered from a painful tumor at the end of the right ring finger. This had commenced without any apparent cause as a painful twitching; a few years later the pain became more intense and continuous. The whole course of the ulnar nerve was painful. On operation a small tumor was found below the skin and lying close to the bone. Microscopically the tumor was fibrocellular with a distinct capsule. The tumor enclosed several nerve endings.

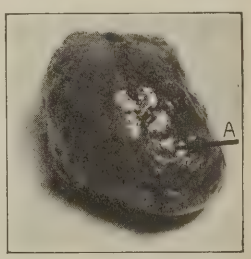

Fig. 2.—Appearance of excised tumor, actual size. A, ulcerated area of skin overlying tumor.

Tissot (7) removed a fasciculated fibroma of the right index finger from a girl of fourteen years. There was no history of traumatism. The tumor was small, mobile, nonfluctuant and painless; the skin was normal. Microscopically the tumor originated from the tendon sheath, and was very hard, whitish in color and woody. Tissot mentioned that Notta (8) reported a case of fibromata of the carpal sheath of the flexor tendons; this tumor was the size of a hen's egg, and was situated between the tendon pocket and the metacarpal bone; it was fluctuant and cystic at its centre. He also mentioned that Woodworth reported a case of fibroma adherent to the finger tendon sheath.

Barbet (9) has recently reported a case of tumor

of the pulp of the right index finger, which he removed from a woman aged forty years. Histologically the tumor was a pure fibroma without any adherence to the skin or the subjacent planes. There was no history of traumatism.

Frank's case (10) reported in 1908, was rather different from those above reported in that the tumor was apparently congenital. Two small growths ap-

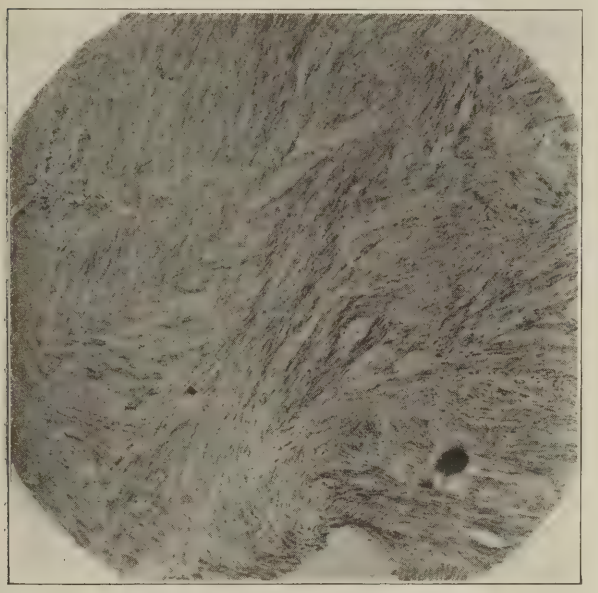

FIG. 3.—Photomicrograph of tumor enlarged 95 diameters 4x16; hematoxyline and eosin stain, Leitz apochromatic.

peared shortly after birth at the terminal phalanges of the fourth and fifth finger of the left hand and were removed. Histologically the tumors were fibromata.

The few cases reported above suffice to show that true fibroma of the finger is rare.

As Virchow has pointed out, the most striking feature of tumors of this kind, which distinguishes them from sarcoma, is that while the growth originates usually from the bone and involves its surface, the mass of bone beneath retains its strength and firmness and is in no way softened, absorbed or carious. A fibroma may, however, arise from the fibrous tissue of the tendon sheath.

There is no evidence that traumatism plays any part in the production of such tumors, although a traumatism may favor its development or even its degeneration into malignancy. That heredity or disposition may be factors seems possible from Frank's case.

True fibrous tumors of the finger are rare; and of the false tumors, fibrosarcomata are the most frequently observed. Fibrosarcomatous tumors generally arise from the tendon sheaths and are variously described as myeloplax sarcoma, giant cell sarcoma, fusocellular and globocellular sarcoma, etc. The lack of uniformity in the nomenclature of these tumors arising from the same tissue and characterized by an abundance of myeloplax cells, is somewhat confusing and seems to need revision.

Rosenthal (11) in 1909 collected forty-seven cases of such finger tumors from the literature, which he classified as forty-one myeloplax or giant cell fibrosarcoma, three spindlecell, one myxofibrosarcoma and two of doubtful type. Tourneaux (12), in 1913, increased the number to forty-eight cases, of which eight were situated on the thumb, thirteen on the index finger, eleven on the middle, eleven on the ring, and five on the small finger.

Myeloplax sarcoma is most frequently observed, and appears to be connected with the fact that the sarcoma develops in the finger where the tendons are almost in direct contact with the bone and devoid of endothelial or epithelial investment.

Sarcoma of the tendon sheath appears to have been first described by Chassaignac (13) in 1852. Heurtaux (14), who investigated these tumors, endeavored to show in 1891 that beside the rapidly evolving proliferating and easily recurring type of tumor originating from the figured connective tissue cells, there is another type distinguished by the presence of abundant myeloplaxas. To this type of tumor he gave the name of myeloma, which term connoted a benign type of neoplasm as compared with the first. This theory was generally accepted until 1909, when Rosenthal (11), from the study of seventy-one general tendon sheath tumors was forced to conclude that there was no essential difference between the two classes of tendon sheath tumor described by Heurtaux, and that all such tumors were malignant.

In the finger the usual site of tendon sheath sarcoma is in the flexor tendon sheaths. Of Tourneux's forty-eight cases, thirty-two originated from flexor tendon sheaths and only sixteen from extensor tendon sheaths. The majority were on the right side. The tumors grow by invading the peritendinous cellular

FIG. 4.—Same as preceding magnified 248 diameters. Note scanty blood supply and typical forms of fibrous tissue cells.

tissues, and progress toward the superficial planes of the skin. The skin over the tumor is usually not involved until perhaps the tumor is far advanced, but is free and unchanged in color. The tumor generally contracts adhesions with the underlying structures and has but little tendency to ganglionary or visceral metastases, although generalization through the blood or lymphatics may occur.

The cases reported by Suter (15), Fordyce (16), Jean (17), and a few others were fibrosarcoma of the finger tendon sheaths. In Suter's case a man injured his thumb eight years previously; there was severe and increasing pain for several years. Histologically the tumor was seen to be in one part a true fibroma, but in another part, especially where the growth joined the bony surface of the phalanx, sarcoma was evident. Fordyce's case was in a child nine months old, the diagnosis being based on a biopsy examination. Jean's case was a fusiform fibrosarcoma originating from the sheath of the common extensor tendon of the fingers.

Sarcoma of the finger arising otherwise than from the tendon sheaths appears to be very rare, and only a few scattered reports occur in the literature. These tumors generally originate from periosteum or from unusual tissue.

Fibrochondroma of the fingers has been reported by Rocher (18), Jacobson (19), and others. Cases of fibroangioma have been described by Tourneux and Lefebvre (20) and by Mermet and Lacour (21). Chandelux (22) and Key (23) described cases of fibromyxoma of the fingers. Vogt (24) reported a curious case of congenital fibrous elephantiasis of the finger.

Mermet and Lacour consider their angiomatous fibromata (two cases) as originating from slight traumatism of the skin. They were dermatofibromata of traumatic origin and purely inflammatory. Both cases began after a slight skin injury.

Lipomata of the fingers are nearly as rare as fibromata, and less than twenty such cases are known. Martin and Grenier (25) have recently reported a tumor of this type on the palmar surface of the left ring finger, which histologically appeared to be of periosteal origin.

Tourneux and Lefebvre's case (20) of fibroangioma was interesting from the point of view that it was probably congenital. The tumor dated from birth and increased very slowly for six years. The authors think that it increased at the expense of the derm, which proliferated profoundly and invaded the periosteum of the phalanx of the middle finger. The histological examination showed that the tumor was a fibroangioma developed at the expense of the derm and was almost entirely composed of fibrous elements, there being but very few connective cells.

There are no special characteristics which distinguish a fibroma clearly from other tumor growths in the finger. A fibroma is likely to be mistaken for the commoner chondromata, but the latter usually develop earlier in life and clinically the growth is less rapid. The hard consistency and smaller size may be of some value in differentiating a fibroma from a sarcoma, but none of these signs are to be relied upon. Ulceration as observed in my own case is unusual, and has only been reported in a few cases of fibrosarcoma. Pain is felt as a rule only if nerve endings are involved in the growth.

Diagnosis can never be certain unless a histological examination be made, and generally this is only possible after surgical removal of the suspected tumor. The most important question in the case of a finger tumor is to decide whether the growth is benign or malignant. A growth slowly progressing for years may suddenly increase rapidly, and then be found to be malignant. Growth may be hastened by a slight traumatism.

Diagnosis of the exact nature of a finger tumor, like that of any other neoplasm, must finally rest on histological examination of the specimen; but a probable diagnosis of malignancy may be presumed from the small proportion of the finger tumors that are benign, from the site, the long duration of the tumor, absence of fluctuation, free movement of the skin over the tumor, and the hard smooth feel of the neoplasm. The tumor usually evolves to an advanced stage without pain, although in Suter's case of fibrosarcoma (traumatic history eight years before) excessive pain was observed for a long time. There was severe pain in only two of the cases of fibrosarcoma reported by Mueller; nor did the tumor until far advanced interfere with the patient's ability to work. In Chisholm's case of true fibroma the constant pain was due to involvement of nerve endings in the tumor.

Treatment of tumors on the fingers can only be surgical. Best results are obtained when operation is early and the tumor strictly localized. In the early stages when the growth is strictly limited or encapsulated, a wide excision with preservation of the tendon, if not involved in the tumor, may suffice; but if infiltration of the sheath and tendon is of such a character that a delicate dissection permits only of incomplete operation, and especially if the presence of malignant tissue is disclosed by histological biopsical examination, then disarticulation or amputation may be indicated. As recurrences of sarcoma of the finger are rather frequent, operative procedure should be radical in a tumor of this type.

In my first case, owing to the tumor being easily disassociated from the surrounding tissue and being encapsulated, with no evidence of malignant histological elements, I felt that excision completely satisfied the conditions. The benign nature of the tumor also would not have justified sacrifice of the finger. In my second case the nature of the growth and its clinical manifestations necessitated more drastic measures.

Some Observations on the Diagnosis of Carcinoma of the Colon and Rectum*

JULIUS FRIEDENWALD, M.D.
and LEWIS J. ROSENTHAL, M.D.
Baltimore, Md.

Carcinoma of the colon and rectum are not uncommon affections, and yet in these diseases the diagnosis is not usually established until late in their course. For, as in carcinoma of the stomach, the diagnosis in the late stages of these affections is extremely simple, while in the early stages, at that period when surgery offers the greatest hope for relief, it is often extremely complicated. This difficulty arises from the fact that tumors in these regions are slow in their growth, metastasizing late and consequently produce few or no symptoms in the early stages, and are thus overlooked until a later period when some complication arises to point to the true nature of the affection.

Growths of the colon and rectum occur according to the order of their frequency in the rectum, sigmoid, cecum, hepatic and splenic flexures; and next to carcinoma of the stomach, carcinoma of the rectum is the most frequent seat of malignant growths of the intestinal tract.

Of the 129 cases of malignancies of the colon recently reported by Erdmann and Carter (1) the rectum was involved in fifty instances (38.7 per cent.), the sigmoid in thirty-seven (28.6 per cent.); the terminal transverse colon, splenic flexure and descending colon in nine (6.9 per cent.); the terminal ascending colon, hepatic flexure and proximal transverse colon in fifteen (11.6 per cent.), and the terminal ileum, cecum and ascending colon in eighteen (13.9 per cent.).

The following statistics of Gant's thirty-two cases of colonic cancer (2) are of interest.

Number	*Age in Years*	*Location*	*Number of Cases*
2	10 to 20	Cecum	3
4	20 to 30	Ascending colon	1
7	30 to 40	Hepatic flexure	4
8	40 to 50	Transverse colon	2
6	50 to 60	Splenic flexure	3
5	60 to 80	Descending colon	1
		Sigmoid flexure	18
		Total	32

In these thirty-two cases eighteen were in males and fourteen in females.

There were sixty-four cases of cancer of the colon and rectum in our series. The following table presents these cases arranged according to sex and location of the growth.

No. of cases	*Location of growth*	*Males*	*Females*
32	Rectum	21	11
20	Sigmoid	16	4
2	Cecum and ascending colon	2	0
4	Hepatic flexure	2	2
1	Transverse colon	1	0
4	Splenic flexure	3	1
1	Ascending colon	1	0
64	Total	46	18

*From the Gastroenterological Clinic of the Department of Medicine of the University of Maryland, Baltimore.

Grouped according to age the sixty-four cases occurred as follows:

Years	*No. of cases*
30 to 40	8
40 to 50	23
50 to 60	19
60 to 70	14

In the diagnosis of cancer of the colon and rectum the age of the patient must be taken into consideration as growths in these regions are not ordinarily observed until past the fortieth year of life, though instances occurring in younger persons are occasionally noted. There were eight cases in our group between the ages of thirty and forty years, of which four occurred before the thirty-fifth year.

SYMPTOMS

The symptoms of these affections vary somewhat according to the region involved as well as according to the extent of the growth. In arriving at a diagnosis the following signs and symptoms must be taken into consideration: :

1. Loss of weight; cachexia, anemia, toxemia and dyspepsia.
2. Localized and general discomfort in the abdomen associated with pain and colic of more or less severity.
3. Evidences of obstruction of various degrees of intensity.
4. The presence of a palpable tumor.
5. Alteration in the character of the stools.
6. Intestinal hemorrhage.
7. Ascites and edema of the extremities.
8. X ray evidence.
9. Proctoscopic signs.
10. Blood sugar tolerance test.

1. Loss of weight, cachexia, anemia, toxemia and dyspepsia.—The onset of carcinoma of the colon and rectum is ordinarily insidious and a considerable period of time often elapses before any of the symptoms noted above are manifested. While loss in weight is an extremely common symptom, it rarely occurs in the very early stages of these affections, and is therefore of but little value as an early sign. Progressive secondary anemia also usually appears late, though occasionally it occurs early, caused by slight but continuous bleeding from the bowel appearing in the form of the occult type; attention to the clinical significance of this sign will again be called later. Secondary anemia is so frequently observed as an initial sign of this disease, that whenever the cause of a progressive secondary anemia is not apparent malignant disease of the bowel should be suspected. Toxemia and cachexia are usually late developments and their significance is similar to that noted in carcinoma of other regions of the body. Not infrequently an irregular type of temperature is associated with the toxemia, though this may, however, manifest itself even early in the course of the dis-

ease. Symptoms of gastric disturbance are not uncommonly observed in the early stages of intestinal growths and not infrequently are so prominent that the primary affection may be overlooked. These symptoms consist mainly of nausea, occasionally vomiting, distention and eructations.

It is interesting, too, to note that there is according to our experience an entire absence or a diminution of free hydrochloric acid in the gastric secretion in many of these cases; a finding observed in fifty-five per cent. of the cases of cancer involving organs other than the stomach.

2. Local and general discomfort in the abdomen associated with pain and colic of a more or less severe type.—Growths in the cecum and ascending colon are usually accompanied by some discomfort in the lower right quadrant often present early in the course of the disease, which is increased by active movements of the body, as jarring, etc. This area is often tender on pressure, not infrequently giving rise to an erroneous diagnosis of appendicitis. Severe pain is rarely manifested unless the growth assumes such proportions as to occasion obstruction, which occurs ordinarily late in the course of the disease for, on account of the usual liquid consistency of the cecal contents, obstructive symptoms are less likely to occur. In other segments of the colon, pain and colic are observed far more frequently, for in these areas the solid feces have greater difficulty in escaping through even a less obstructed bowel. In carcinoma of the rectum, pain is most pronounced when the growth is situated low or when it has caused obstruction. It is frequently associated with a sensation of fullness in the lower bowel and pain on defecation with a feeling of incomplete evacuation of the bowel. Sigmoid carcinomata often give rise to fulness and discomfort in the left lower quadrant, which is increased by pressure in this area.

3. Evidence of obstruction of varying degrees of intensity.—Evidence of obstruction as a rule appears late in the course of carcinoma of the colon and rectum. Obstruction may be of the partial or complete type depending largely upon the location and extent of the growth. The presence of obstruction is revealed by the onset of pain already noted, progressively increasing constipation, as well as by careful proctoscopic and x ray examinations. Not infrequently, obstruction is also indicated by the appearance of visible peristaltic movements and patterns extending across the bowel often associated with tympanities.

4. Presence of a palpable mass.—At times, especially when the mass is located low in the colon, signs of acute obstruction with all the symptoms usually noted in this affection may occur and again disappear at varying intervals under treatment before evidences of complete obstruction are revealed. In several instances in our series this sign was the first subjective as well as objective manifestation pointing to the presence of the growth. The presence of a palpable mass is usually a late manifestation of colonic cancer, and especially in those instances in which the growth is located in the cecal region. It is often observed only as an indefinite resistance associated with much spasm. Tumors at the hepatic flexure are ordinarily difficult to palpate, while those in the region of the transverse colon and splenic flexure are less so. Carcinomata of the splenic area and descending colon must be differentiated from renal growths. In carcinoma of the rectum digital examination will usually reveal an early growth in this area. According to Yeomans (4) in 110 cases the tumor was palpable in ninety-nine and only in eleven cases, or ten per cent., was the proctoscopic examination required to determine the presence of a growth, which could not be reached with the palpating finger.

Attention must again be directed to the importance of routine digital examination of the rectum early in all patients manifesting symptoms referable to the gastrointestinal tract. Not infrequently the explanation will become evident at once by this simple method of investigation.

5. Alteration in character of stool.—Constipation is often the earliest sign of carcinoma of the bowel. It may appear suddenly but more frequently its onset is gradual becoming progressively more intense. It is not necessarily dependent upon the degree of obstruction or extent of the growth. Alternating constipation and diarrhea is not uncommon and the stools are frequently ribbonedshaped, short or long, or have the appearance of round balls covered with mucus and blood. There is usually a sudden desire to evacuate the bowel often followed by an explosive unsatisfactory stool, unless the growth is situated near the anus, when there may be only a discharge of slight amounts of bloody mucus. A secretion containing mucus, blood and pus due to the tumor is the frequent cause of moisture of the external anal area. The stools are frequently foul smelling due to the expulsion of degenerated portions of the growth.

6. Hemorrhage.—Profuse hemorrhage is not frequent in cancer of the colon and rectum; though as has already been pointed out, the discharge of bloody mucus is quite common. The stools frequently contain occult blood even in the early stages of the disease; in our experience when this is once observed it usually continues during the entire course of the disease. The presence of this sign in a patient over forty years of age with sudden onset and progressively increasing constipation is extremely suggestive of the presence of this disease.

7. Ascites and edema of extremities.—Both ascites and edema are usually observed as late manifestation in carcinoma of the colon and rectum. The edema of the extremities is not usually extensive and is frequently only transitory disappearing and recurring during the progress of the disease (edema fugax).

8. Röntgen ray evidence.—The x ray is of the greatest help in the diagnosis of colonic growths and is often the only means of pointing to an early diagnosis. According to Carman seventy-five per cent. of tumors of the colon can be detected by means of the x ray, the most important evidence in this direction being in the form of a filling defect and the presence of obstruction. Rectal growths are, however, frequently overlooked by the barium enema.

The opaque enema must be observed fluoroscopically and plates should also be taken. The x ray is not of as great value in the diagnosis of early carcinoma of the cecum as it is of other portions of the colon. The filling defect is often unilateral or may have the appearance of a concentric obstruction. Great care must be exercised to be positive of the

constancy of these findings. In a special instance which has come under our attention in which a capable röntgenologist made a diagnosis of carcinoma of the ascending colon, and in which the diagnosis was confirmed by all the usual methods practised by röntgenologists, the filling defect and partial obstruction were found due to the dragging down of the bowel by adhesions, connected with an inguinal hernia. It must also be borne in mind that spastic and reflex conditions may lead to errors in diagnosis. It is not uncommon to observe a large persistent filling defect in a definite area of the colon simulating carcinoma and continuing over a period of hours, which will disappear when atropine is administered in full doses.

9. Proctosigmoidoscopy.—By this method growths in the rectum and sigmoid may be visualized and the size, position, motility, as well as ulcerations and adhesions to neighboring organs, determined. In all chronic disturbances of the bowel, no matter what their nature may be, this method of examination should never be neglected. When on palpation of the rectum a growth cannot be detected, it is often possible even to visualize a mass in the bowel by means of this method of examination, as far up as the distal sigmoid.

10. Blood sugar tolerance test.—According to Friedenwald and Grove (5) there is present in carcinoma of the gastrointestinal tract usually a rather characteristic curve of sugar tolerance, which differs somewhat from that observed in carcinoma of other regions of the body. The curve of this affection usually presents a high sugar content even in the fasting state followed by an initial rise up to 0.23 per cent. or higher within forty-five minutes after the ingestion of the dextrose remaining at this level for at least two hours and rarely at any time during this period falling below 0.2 per cent. This test is rather distinctive so that it may render valuable assistance as a means of differential diagnosis between carcinoma and other diseases of the gastrointestinal tract. The value of this test is illustrated by the following case.

Case.—C. S. I., male, aged fifty-four years, had been affected with indigestion for four months. At the onset, he was taken with an acute attack of pain in the lower right quadrant of the abdomen, and a diagnosis of acute appendicitis was made. Since then there had been constant indigestion with general discomfort in the abdomen, pressure, distention, loss of appetite, eructations, extreme constipation, and loss of thirty pounds in weight. On palpation a mass was noted in the right lower quadrant with extreme tenderness in this area. The blood sugar tolerance test revealed a definite cancer curve. At operation by Dr. J. M. T. Finney a carcinoma of the cecum was revealed, and resection was performed; no metastases were noted. The patient made a good recovery, and when a subsequent blood sugar tolerance test was made two months following the operation, a perfectly normal curve was revealed.

In drawing our final conclusions concerning the significance of the various signs and symptoms of cancer of the colon and rectum, it is quite evident that many are general manifestations frequently present in other intestinal affections, and not characteristic of these conditions alone, while those which are more characteristic are usually late developments. On this account the late diagnosis of cancer is rendered exceedingly simple, while on the other hand, the early diagnosis is usually difficult.

In reaching definite conclusions it is, therefore, important to rely not upon a single sign or symptom, for there are no pathognomonic signs of early cancer, and only after a critical review of the history, physical examination and study of the symptoms, including examination of the stools can definite conclusions be drawn. We must take into consideration in our diagnosis the age of the patient, the history of the affection (that is, its onset in the midst of good health), loss of weight, anemia, dyspeptic signs; the local and general discomfort in the abdomen associated with pain of a colicky character, evidence of obstruction, the presence of a palpable mass, and intestinal hemorrhage. In addition, we have the evidence afforded by the digital and x ray examinations, as well as by the proctoscope.

But we rarely have all the signs present in early cancer of the bowel and in most instances usually there are so few manifestations that the diagnosis may be impossible, while in others the early recognition may be masked by the presence of an atypical symptomatology. The general condition of the patient may be extremely good in the early stages of the disease, remaining so even until the first appearance of obstructive signs. It is also a well recognized fact that palpation of these growths (not including those in the rectum) is ordinarily extremely difficult in the early stages, and this difficulty may continue until obstructive signs arise due in part to the pressure produced by the hard fecal masses against the tumor mass.

Evidence of stenosis of the bowel, usually the first alarming manifestation, occurs ordinarily late in the course of the disease and increasing constipation which is frequently an early sign may not appear until a fairly marked degree of obstruction has been produced; though on the other hand, it may arise entirely independently of the obstruction in the course of this affection. A further difficulty may occur in that carcinoma of the bowel may appear in individuals previously constipated for years, and in consequence the onset of this disease may be entirely overlooked.

It is also important, too, to remember that this affection usually appears at the age in which arteriosclerotic changes have already manifested themselves on account of which there are retrogressive changes and impaired metabolism with loss of strength and anemia presenting symptoms often akin to those of cancer. Further difficulties often arise by the occurrence of intestinal cancer in patients affected with some preceding affection such as diabetes, Bright's disease, cardiac affections or chronic infections; on account of which there may be marked emaciation, loss of strength and intestinal disturbance. Finally, there still remains another group of cases, the latent forms in which symptoms are not revealed until late in the course of the disease.

Again cancer of the bowel may occur in young individuals. Erdmann and Carter report a case at the age of twenty-two and Yeomans's six cases between the ages of ten and thirty years; and we have had one of cancer of the rectum under our care at the age of twenty-five years. The diagnosis in these cases is often extremely difficult.

Cancer of the bowel must occasionally be differentiated from other diseases associated with loss of flesh, such as pernicious anemia, serious forms of colitis, tuberculosis of the bowel, diverticulitis, prostatitis, hemorrhoids and even fecal impactions.

As we have attempted to point out the difficulties encountered in arriving at an early diagnosis of intestinal cancer are at times extremely great and in as much as surgery offers the only cure and then only when the diagnosis is made early the question of early diagnosis is of paramount importance. As yet, it is frequently impossible to reach very definite conclusions at the early stage, except in rare instances. But it is extremely important to view with suspicion all patients over forty years of age who present a progressively increasing constipation associated with the passage of blood in the stools even though this blood be but of the occult type. In all such instances routine physical including digital as well as proctoscopic examinations should be made and if necessary these procedures should be augmented by thorough and repeated x ray studies.

It is evident, therefore, that only by means of most careful investigations into the signs and symptoms, together with painstaking examinations, that we can hope for an early recognition of cancer of the colon and rectum at that period only when a radical cure may be expected from surgical intervention.

The Effect of Sunlight on Growth and Development

W. T. BOVIE, Ph.D.
Boston

In an experiment undertaken at the University of Maine in the summer of 1924, a clutch of about 250 chickens was divided into six lots. All of these were housed in a greenhouse and received the same food and other treatment (chick grain, dry mash, sour milk, and rock grit, water and dust baths) except that lots C and D had green food in addition and lot F had a small amount of codliver oil added to its food. Lot A ran out of doors during the day; lots B and C were exposed for twenty minutes each day to the light of a mercury vapor arc in quartz; lots D, E, and F received light only through the glass roof of the greenhouse.

At the end of four weeks the chickens in groups D and E had less appetite and were less vigorous in their movements than those in the other lots. Those in lot F seemed to have less appetite than those in lots A, B, and C. In other words, only the chicks in groups A, B, and C were normal in every respect.

These differences became more marked at the end of the fifth week. The chickens in lots D and E were evidently suffering from "weak legs," were unable to stand squarely on their feet and had to use their wings for additional support when moving about. Gradually, their nails became long and curled, the bills soft and the plumage ruffled. At the end of two months the chicks in the first three groups were nearly twice as tall as those in lots D and E and were strong and sturdy in every way. In the last thirty days of the experiment the chicks in lots A, B, and C gained twice as much in weight as those in lots D and E.

The chickens in lot F which received the codliver oil had poor appetites and grew so slowly at first that they remained throughout of smaller size than those of lots A, B, and C.

X ray photographs showed that in lots A, B, and C the leg bones were long, straight and well calcified. In lots D and E the bones were short and weak for the deposit of lime and phosphorus salts in the bones were very deficient. In lot F, the bones were well calcified but short.

The development of secondary sex characters paralleled the development of the bones. It is also worthy of note that while but one chicken died out of all those in lots A, B, and C, there were fifteen deaths among the chickens in lots D and E.

It would appear that there was some environmental influence acting on the chickens in lots A, B, and C that was not acting upon the chickens in lots D and E. As the environment was the same in every respect except the light that they received, there must have been something taken from the light as it passed through the glass roof of the greenhouse.

Wherein lies this difference? Sunlight contains heat, visible light and rays invisible to us, known as ultraviolet, extending down to wave lengths of about 0.29 microns. Glass transmits some of the heat, most of the visible light and ultraviolet down to wave length of approximately 0.31 microns. This very narrow band of sunlight between wave length 0.29 and 0.31 microns does not, then, pass through glass, but this light, together with other wave lengths down to a little less than 0.20 microns, does pass through the quartz walls of the mercury vapor arc lamp.

The chickens in lots D, E, and F, then, did not receive light of shorter wave length than 0.31 microns, while lot A received light to 0.29 microns and lots B and C received light down to 0.29 microns in wave length. As the chickens in lot A developed normally it is therefore evident that the difference in the physiological effect of the light on the various groups must be ascribed mainly to this narrow band, a band so narrow that, by analogy, it might be described as

a very pure spectral "color" lying at the extreme range of sunlight.

Why are the antirachitic properties of sunlight restricted to this narrow band? Because, while visible light readily passes through unpigmented protoplasm, in this particular region (and beyond it, on the short wave length side), light is very strongly absorbed by protoplasm and, as was stated by Grotthus over a century ago, only the light that is absorbed can bring about photochemical change.

"Visible light" is valuable to us, because when falling on the pigmented rods and cones of the retina it enables us to see. The energy of sunlight in both the heat and ultraviolet regions of the spectrum is absorbed by unpigmented protoplasm and it has been found by experiment that these rays are necessary for normal growth and development.

Plants bend toward the light and they are sensitive to lights of extremely low intensities if only the light acts for a sufficient length of time. Bunsen and Roscoe, studying the action of light on a photographic plate, found that a constant degree of blackening would be produced by any intensity of light if only the time of exposure was reciprocally adjusted so that the product of I times T would be a constant. Blaau found that the same was true for the bending of the oat seedling, over an enormous range of intensities. As this constant blackening of the photographic plate is unquestionably due to a constant amount of photochemical product it would appear that the light in like manner produces also a photochemical product in the plant. The researches of Blaau indicate that response occurs only when the amount of the photochemical product reaches a certain minimal value.

Only the very tip of a seedling is light sensitive, but the bending occurs, always, a short distance from the tip. It is evident that there must be a transfer of the photoproduct from the point of origin to the point of effect. If we cut off the tip, the plant is "blind." But if the tip is stuck on again, in the original position with a thin layer of a ten per cent. solution of gelatin, though the organic continuity is broken, bending occurs. This makes it seem probable that it is not stimulus directly but a water soluble photochemical product that diffuses through the gelatin and occasions the bending. It is likely, even in the uninjured plant, that bending occurs only as the photoproduct diffuses to the bending region.

The extreme sensitiveness of plants to light would indicate that only a very small amount of the photochemical product is necessary to produce bending, but whether this product, diffused to the bending region, causes the changes that result in bending, or whether it initiates a chain of chemical changes so that the effect is amplified, we do not know.

Two things occur in the growth of plants: an increase in the total amount of substance and a modification of substance into structural elements, or differentiation. These are, to a degree, antagonistic, for as differentiation occurs, growth is prevented. The transfer of the photo product, then, formed in greater amount on the lighted side and diffusing most readily downward along the vessels, causes a differentiation of tissues and checks the growth on the illuminated side while on the other side increase in volume still occurs. The plant therefore is bent to the light.

Light influences the rate of growth but does not control it, for while most plants grow most rapidly at night, they also continue to grow during the day. Most plants cannot grow and develop properly in total darkness. A microscopic examination of their tissues shows profound modification in the cell structure. They do not show the same degree of morphological differentiation as is found in corresponding organs of the same age that have been grown in the light. They are more nearly in an embryonic condition.

On the other hand too great an exposure to light may result in a premature differentiation producing dwarfs; or the whole process of development may be thrown out of order, producing monsters.

Sachs, after extended experiments concluded that there were specific formative materials for the various organs of a plant and that these were not necessarily formed in the place where they were to be used. MacDougal states that the physiological effects of exposure to light may be long delayed and may even carry over into a succeeding season. Impulses may even be communicated to organs not formed at the time the stimuli were received.

The mechanical structure of a plant or of a bone is laid down in accord with the mechanical stresses put upon it. Koch states that this is true of a bone, even to the minutest detail. Even after a bone is formed, a fracture, or even a continued change of posture will alter the structures already laid down, through solution and redisposition until the pattern corresponds to the changed condition.

The deposition of bony material in a developing child is but a process of tissue differentiation and in the absence of ultraviolet light it does not normally take place properly.

It is known that ultraviolet light does not penetrate far enough to reach the bones. It is absorbed at and near the surface of the body and its stimulating action must therefore be transmitted in some way to the developing bones.

We have seen how in plants which have no nerves, the stimulus produced by light seems to be transferred through the medium of a water soluble photochemical product, to places where differentiation occurs. In animals the same thing seems to be true in many cases, and it is also true that the product, formed in plants or other animals, may be taken in with the food. We know that codliver oil is antirachitic; and certain other substances, as lettuce, cottonseed oil or dried milk that have been exposed to ultraviolet light, have the same property. At least the diet stimulates normal differentiation.

When we expose a photographic plate in the camera, photochemical changes occur in some of the silver salts, bringing them into a developable condition. We say the light has produced a "latent image." This is not the actual image that is produced later, upon development. This is produced by the reduction of the silver salts, while the developer is oxidized. This exposure may be made months before the plate is developed.

A baby's arm may be exposed to ultraviolet light of a suitable wave length. The photochemical change produced by the light in the tissues or in the blood may be compared to the latent image on the plate.

When this photochemical product is brought into contact with embryonic bone tissue the latent image is "developed" as chemical interactions that have to do with the metabolic changes that occur in connection with the differentiation of bone tissues. The radiated foods in the experiments of Hess and Steenboch may act in a like manner. Physiologists have named substances like those contained in cod-liver oil, which catalyze certain physiological processes, "vitamines."

Whatever theories are proposed to explain the reactions, the fact remains that most plants and animals, including man, are as dependent upon the ultra-violet energy of sunlight for normal growth and development as they are upon the heat energy of sunlight. Other physiological functions besides bone development are interfered with when the organism is deprived of this kind of radiation. The body is more susceptible to the inroads of disease. A well sunned body furnishes a high degree of protection against tuberculosis and the progress of the disease, even after it has been contracted, is often quickly and permanently checked. Window glass has unquestionably accelerated the speed of civilization, but man has paid the price.

New Clinical Aspects of the Steinach Operation

HARRY BENJAMIN, M.D.
New York

In presenting another paper on the Steinach method of socalled rejuvenation, I have several purposes in mind. First of all, after having operated on 114 patients, partly—in the sense of Steinach—for the purpose of retarding age, partly to influence the endocrine system, I feel justified in looking back on the results in general and giving a survey of all my experiences. I shall discuss technic, indications, and contraindications, and in order to enable the practising physician to form a proper judgment of the therapeutic value of the Steinach operation, I shall, on the basis of these 114 cases, indicate the possibilities as well as the limitations of this procedure, reporting both failures and successes. Some of the patients have been observed for over three years and a judgment as to the permanence of the results is therefore well justified. I have taken great care to judge these results very conservatively, underestimating rather than overestimating them in doubtful instances.

In a paper like this, it is not quite possible to follow the usual rules guiding medical publications, since the practice of the Steinach methods does not exclusively concern people suffering from a definite disease. In the majority of cases, these patients come to seek relief from symptoms of premature or physiological senility with a decline of vitality. It is, therefore, quite difficult to judge the value of this treatment, because the patients will not as readily undergo repeated examinations as would a sufferer of some welldefined disease. Besides, the treatment, especially in women, is practically always ambulatory and a majority of patients live far away, so that written reports often have to replace physical examinations. This accounts for the lack of exact clinical data. But if we hear over and over again that certain subjective symptoms have been ameliorated in a very identical way, we are justified in attributing the effects to the cause.

In my opinion, the frequency and regularity of these subjective improvements lent them already the strength of an objective proof. It is only necessary to compare with my own reports those of Cardenal, Chetwood, Haire, Lichtenstern, Sakaki, Sand, Schmidt, Vecki, Walker and Cook, Wolbarst, and others.

In order to gain as many objective data as possible I have followed these rules:

1. Wherever possible, frequent reexaminations were made in order to determine objective changes. Thus, blood pressure, hemoglobin and skin reaction were examined, changes in distribution and color of hair noted, weight controlled, and physical strength measured by means of the dynamometer. Occasionally a specialist determined the eye and ear status.
2. By sending out questionnaires, written reports were solicited, especially from the intelligent and critical patients and from colleagues on whom I had operated.
3. Where possible, reports from family physicians were requested regarding the patient's condition.
4. Occasionally, relatives and friends were asked to report their observations of changes in the patient.

The literature on the clinical aspect of the subject contains a considerably larger number of successful reports than unsuccessful ones, and it is evident that any antagonism toward Steinach's work and the practice of the operation that bears his name, is not so much based on negative clinical observations as it is directed against the echo which the entire subject found within the laity, and not the least against the word rejuvenation itself. The attacks of theorists and pathologists are naturally concerned with Steinach's theories and explanations of his clinical results with which these laboratory workers have no or too limited an experience.

Steinach's theory is that by ligating the vas deferens, the discharge of spermatozoa is interfered with. The result is a back pressure into the testicle and a pressure atrophy of the seminiferous apparatus. The place of the disappearing seminal cells is taken by the proliferating interstitial (Leydig) cells, which, in Steinach's opinion (corroborated by Athias, Kuntz, Haberland, Lillie, Sand, and others and especially Lipschuetz), are the principal inner-

secretory organs of the testicle. Their increasing number produce an increased output of testicular hormones with subsequent tonic effect on the rest of the endocrine system.

In a recent publication, Schinz and Slotopolski (1) disagree decidedly with this theory, but in contradistinction to other opponents of Steinach's theory, admit a favorable clinical effect of vasoligation. Their explanation is (like Stieve's and others) that the back pressure destroys the seminal epithelium and that the absorption of these disintegrating cells is responsible for this clinical result, either acting directly on the organism or indirectly through other endocrine glands. It is not my intention here to try to decide this question, which, after all, is not a clinical but a histological and biological problem. However, considering the literature and Steinach's original transplantation experiments and also deductions from my own clinical observations, the greater probability seems to rest with the Leydig cell theory.

Another recent article on the subject is by Hans Steindl (2). His conclusions are of little value, since he has not used the Steinach operation for its principal indication: senility. Steindl has, for instance, operated in cases of cancer, where only temporary benefits could be expected, and these were fully obtained. He also operated on patients with psychic impotence, which is no indication at all, and —*experimentis causa*—cases of Parkinson disease, with naturally not more than doubtful or passing benefits. On the whole, Steindl has fully confirmed all that has been claimed for the Steinach operation in those cases that he selected for operation. In spite of that, he has come to general negativistic conclusions. This fact seems to me of more value for a criticism of the author's psychology than of the merits of the Steinach operation.

It is not the purpose of this paper either to review the entire literature, which has already assumed impressive proportions. For those interested deeply enough in the subject, I would only mention that the recently published book by Peter Schmidt (3), as well as the book by Norman Haire (4), offer quite a complete and practically up to date bibliography, also Paul Kammerer's (5) book on the prolongation of human efficiency.

The problem of rejuvenation is likewise touched upon in two other books dealing with the testicle and its functions. The first one is by Alexander Lipschuetz. Here Steinach's original experiments find fullest recognition and confirmation. The other book is by Max Thorek (7). It merits becoming a standard textbook on this particular subject. Both books contain a splendid bibliography of the entire field.

Before I come to my case reports, I would like to describe a few points in the technic that I have used in the majority of my cases. I always do the operation on the scrotum. There is no difficulty in rendering these parts aseptic. The pubes and scrotum are carefully shaved. The field of operation is thoroughly cleansed with soap and sterile water, dried and wrapped in sterile gauze until the moment of operation. No iodine or alcohol is used because I have frequently found that the patient complained of this application much more than of the actual operation. With this method of preparation, I have never seen even the slightest infection. The operation is performed in such a way that the vas, which can easily be felt through the skin of a relaxed scrotum, is brought close under the skin by manipulation with the finger. In this position, it is held by the assistant. The skin is anesthetized with one per cent. novocain and one to ten thousand adrenalin and then incised. The vas is readily found and is carefully isolated and stripped of accompanying structures. In a short and contracted scrotum, the vas cannot always be felt and not easily be brought to the surface. In those cases I have found it useful to apply a sterile hot towel for five minutes over the scrotum. This causes sufficient relaxation to isolate the vas with the finger. In cases where this easy access to the vas cannot be accomplished, the cord is exposed by an opening long enough to allow two fingers to enter the wound. With these two fingers the vas is differentiated and then seized with a toothed forceps. By careful dissection with a blunt forceps and gauze, the vas is isolated without injuring any accompanying bloodvessels or nerves. After the organ is thus thoroughly stripped for a distance of one or two inches, it is ligated with silk in two places and a piece between these ligatures about one inch long is resected. This, at least, is the most frequently used technic. The main object is to prevent reopening of the vas and recommunication of the two ends. A double ligature of the lower stump is advisable. In order to use as little foreign material in ligating as possible, I frequently do the following: I ligate above with chromic catgut, since reopening of the upper stump plays no part in the effect on the testicle. The lower ligature consists of medium sized, doubly sterilized silk. I cut the vas near the upper ligature and the piece between this cut and the lower silk ligature is bent down in a look and the same silk ligature is used to ligate the vas a second time. Again using the same thread of silk, this lower stump, now a loop, is sewed into the surrounding tissue to preserve testicle suspension. A few catgut stitches close first the opening in the tunica, then in the skin, after all possible bleeding has been stopped. A sterile dressing is kept in place by a large suspensory, which is left on for about eight or ten days. After that time the incision is completely healed. With this technic the operation has always been absolutely painless and a complete surgical success.

Unfortunately, I have had more than one opportunity to see unsatisfactory surgical and negative endocrine results, due to a wrong technic. I therefore believe that a painstakingly correct technic is essential for success.

Up to the time that this paper goes to press I have, as stated above, operated on altogether 114 patients. Some of them are decidedly too recent to warrant an opinion regarding results. In these cases, as well as in all the instances where I was unable to communicate with the patient, I will only mention the character of the case briefly in the attached tables, and report in more detail only twenty of those cases that seem distinctly instructive and characteristic in one way or another.

In August, 1922, I described eight cases in detail (8). In November, 1922, I reported twenty-two cases, including further details on the first eight cases (9). I would like to classify the results the same

way as I did in 1922, and may be allowed to repeat this classification here with a slight modification:

1. Positive, if there was clear evidence of an objective beneficial effect.

2. Subjectively positive, if the patient claimed an improvement of his symptoms only.

3. Doubtful, as to clinical interpretation.

4. Negative, if no changes at all occurred attributable to the operation, after a period of six months or more.

Regarding the last group I would like to mention that some of the cases reported as negative may yet show results at some later date. From verbal and written communications of Professor Steinach, who does not himself publish any results, I have learned that in several cases definite improvements (especially regarding sexual potency) occurred only after a year and even considerably later. (Vide my own Case VI.)

I omit from the list of the twenty-two cases those eight cases which I could not follow up. Of the remaining cases these are the important ones:

Case III.—College professor, aged fifty-five. Reported positive seven months after the operation. Since then the patient has improved still further. He was last examined in December, 1924, exactly three years after the operation, and was found to be in excellent general health. His improvement in physical and mental strength and endurance has continued and his former complaints (unusual tiredness, rheumatic pains, mental depression, frequent urination), have not returned during the three years. He has kept his gain in weight and his hair has assumed a slightly darker shade. There has been, however, no change in his sexual desire or ability, both of which play a minor part in his life. The operation was done unilaterally and the result certainly refutes the theory that the operation produces a merely passing stimulation.

Case VI.—Contractor, aged fifty-eight. Was reported strongly positive five and a half months after a unilateral ligation. Nearly three years later the patient reported a continuation and further increase of improvement. He described his physical and mental strength as "very good" and "as good as ever," his appetite and digestion as splendid, his sexual ability as very good. He had gained ten pounds, and was, on the whole, three years after the operation, just as satisfied and apparently more so, than when the first report on his case was made. Although no reexamination could be made recently, I feel justified from the written report, knowing the patient's critical mind, to regard his case as evidence of a lasting benefit. This lasting benefit is still more evident in the following case:

Case VIII.—Editor and former clergyman, aged fifty-eight. Unilateral operation March, 1922. Was reported positive (except sexually), five months after operation. This very intelligent and highly educated man wrote in December, 1924, two and a half years after operation, a letter from which the following lines are taken:

"This past year has been a strenuous one for me. I have worked hard physically and mentally—usually ten to fourteen hours a day including half the Sundays. Have had an unusual amount of mental strain to bear, but have come through in splendid shape. Am sure the operation made this possible for me."

He further reports his digestion to be better and that his formerly frequent (pituitary) headaches, which were gone already five months after operation, have not returned. He has grown somewhat balder. His sexual ability has not improved.

He says, "I am willing to attribute all I have mentioned to the operation, since there is nothing else that could have caused the change." His hopeful outlook on life is shown in the last sentence of his letter, written on the last day of 1924.

"I have a hard year of work ahead, and it will be my sixty-first year on earth. It should be my best year and I think it will be."

Comparing this frame of mind and general state of health to the one of premature senility in 1922, it is rather difficult not to be fairly enthusiastic about the result accomplished in this case.

Case XII.—Naval officer, aged fifty-six. Was operated on in April, 1922. The diagnosis was angina pectoris and beginning arteriosclerosis. The case was not classified when first reported. Twenty-six months after operation the patient stated that his general health was good. His attacks of angina were still present but not so bad, his blood pressure somewhat lower than before the operation, his sexual ability fair and his digestion improved. He recently graduated from a college and is convinced that he has derived benefits from the operation. The improvement in this case is only moderately positive but of prolonged duration.

Case XVII.—Clerk, aged fifty-five. On June 1, 1922, Dr. H. performed a laparotomy and found an inoperable cancer of the head of the pancreas. Simultaneously, I performed a bilateral vasoligation in the hope of checking the steadily increasing cachexia. Two months later I was gratified to find the cachexia at a standstill and the patient's weight stationary. Four months later I was informed that in spite of extensive traveling, the patient was still holding his own. The result in this case was classified as doubtful. I have heard that the patient has since died but it seems to me that the operation somewhat retarded the fatal issue.

Case XVIII.—Physician, aged sixty-seven. Reported partially positive five weeks after a unilateral operation had been performed on account of beginning senility and arteriosclerosis. One and a half years after operation the doctor wrote that he had gained some weight, that he had as much strength and endurance "as he ever had," feeling no fatigue after a strenuous game of golf. The color of his hair had not changed but some new hair had grown on his head. His sexual ability is "on the wane." His memory is unchanged and his ambition as good, if not better than it was. His blood pressure before the operation was 195 with a pulse pressure of 85. One and a half years after operation he reports it as 180 and pulse pressure 60. He feels that the operation has done him good. I would classify his case as positive showing moderate but certainly not transitory benefits.

Case XX.—Dyer, aged thirty-nine. The case was diagnosed as hypogonadism and was reported positive five weeks after a unilateral operation; has not improved any further but has kept his gain when last examined in November, 1924 (twenty-seven months after operation). The erections had become stronger

but the ejaculations were not influenced. His general health had remained good. He has derived a lasting moderate benefit.

Drawing conclusions from the study of these cases, I can briefly say that those patients reported positive in 1922 are still positive today as far as the observations could be continued, the improvement even having increased in some of them. One negative case remained negative, and doubtful cases (IX and XIV) remained doubtful. (Vide tables.) The most important point is the definitely established fact that in none of these cases one can speak of a temporary benefit derived from the operation. I feel justified, since no relapse has occurred in over two or three years, in pronouncing these cases as permanently benefited. I shall be able to further strengthen this conclusion with a number of other cases not yet reported.

Case XXIII.—Salesman, aged fifty. Principal symptoms and complaints: For many years attacks of depression. Since two or three years continuous state of depression.

A diagnosis of manic depressive insanity was made. In September, 1922, a unilateral operation was done. One month later his depression had disappeared. He was perfectly comfortable. Had gained ten pounds in weight. His blood pressure, before the operation, was 155/100, and after the operation was 120/85.

Examination on April 3, 1923, seven months after operation: The patient remained well until attack of influenza in February, 1923. Since then has had two attacks of depression. Semen contained spermatozoa. On urgent request of the patient another bilateral operation was performed on April 9, 1923 (Case XXXVIII). On the side of first operation, the ligature was placed below the scar; on the right side, multiple hydrocyles of the cord were removed at the same time with the ligation. An immediate improvement resulted with a drop of blood pressure to 115/80. However, another moderate depression occurred three weeks later and since that time until now (two and a half years after operation) there have been occasional attacks of depression lasting from one to three weeks with a perfect state of wellbeing in between. Organotherapy by mouth and x ray treatment to the pituitary and the thyroid have failed to check the attacks of depression completely, but they are decidedly less intense with no accompanying suicidal tendencies. I feel that the result of the two operations is a partial one. The manic depressive insanity has not been cured but the constant state of depression has been changed into a condition of years ago, attacks of depression being less deep and less frequent. The result was partially positive.

Case XXIV.—Laborer, aged thirty-five. Diagnosis of impotentia sexualis with hypogonadism was made. Vasoligation was performed twice on the right side, first in September, 1922, with an immediate sexual stimulation and distinct general improvement. Six months after the operation, he had gained weight and felt physically and mentally stronger but the sexual stimulation had somewhat subsided. A second operation was performed December 6, 1923, on the same side nearer to the epididymis. The vas was found extremely atrophic. A small part of it was resected and examined microscopically. The report of the pathological laboratory was as follows:

"Microscopic examination of sections made both longitudinally and transversely show a tube, the inner lining of which consists of a layer of epithelium of the low columnar type, which epithelium is supported by a rather dense laminated hyaline connective tissue. In sections made the long way of the specimen there are from three to five spermatozoa found in each section."

Since the resected piece of the vas was situated below the first ligature, this examination shows that a regeneration of the spermatogenetic tissue had taken place within the fourteen months that had elapsed since the first operation. This finding is in accord with those of Steinach's animal experiments. In February, 1924 (two months after operation) the potency was again distinctly improved, intercourse normal. Last examination March, 1925, (one and a half years after the second operation); the old disability had returned.

In spite of temporary improvement, I am inclined to call the result negative. I believe that psychic inhibitions are mainly responsible, the endocrine stimulation or possibly autosuggestion having succeeded to overcome these inhibitions only temporarily. Psychoanalysis was not advised as the low intelligence of the patient did not seem to warrant such course of treatment. Here one could indeed speak of a temporary result.

Case XXXIV.—Laborer, aged fifty-eight. Principal symptoms and complaints: Felt "getting old," weakness of eyes, easily fatigued. Acne for many years in face and on back. Weight 137 pounds. Pulse 78, Blood pressure 140/95. Strength in right hand measured by dynamometer 55, left 75. Prostate slightly enlarged. The diagnosis was incipient senility, and acne gangrenosa.

A bilateral operation was done in March, 1923. Last examination, March, 1924 (one year after operation) generally well and fit for work. No fatigue. Acne practically disappeared. Pulse 68. Blood pressure 125/85. Dynamometer: right 65, left 85. Weight 136 pounds.

The result was positive. (The cure of the acne is especially instructive on account of the known connection between this affection and endocrine gonadal function).

Case XLVII.—Painter, aged forty. Principal symptoms and complaints: Very nervous, easily exhausted, unable to work as formerly. Decline in sexual potency. Frequent emissions, depressed, restless and worried. Physical examination: Negative. Weight 155 pounds. A diagnosis of premature senility and sexual neurasthenia was made. A unilateral operation was done August, 1923.

One month later there was distinct improvement, much better balanced. Fewer emissions. Was working regularly for first time in many months.

Last examination: June, 1924 (ten months after operation). In excellent health. Weight 169 pounds. Hair and beard growing stronger. Nails not as brittle as formerly. Enough selfconfidence to contemplate marriage.

Case LVII.—Dramatic critic, aged sixty-seven. Principal symptoms and complaints: For eight to ten years gradually decreasing working ability. No sustained effort possible. Easily fatigued. Often depressed. Decline in sexual strength. No other

physical complaints. Pulse 76. Blood pressure 125/75. Weight 141½ pounds. Skin reaction faintly red. Testes somewhat undersized. A diagnosis of incipient senility was made. September, 1923, a bilateral operation was done.

This patient, whose business it is to be critical, began to improve about one month later, the improvement steadily increasing.

In March, 1924 (six months after operation), patient felt more "alive and buoyant." His mind was clearer and more resilient, he was able to work quicker and without being fatigued. His physical condition was about the same as before the operation. His sexual strength had decidedly improved. His wife said "he is decidedly less nervous."

January, 1925 (one year and four months after operation), patient was even better than one year ago. He felt young, energetic and cheerful. During the end of the theatrical season, patient was able to do his work only with great effort and with the help of tonics. Last year and now, he felt at the end of the season "fresh as in the beginning." He became normally tired after a strenuous day but recuperated much quicker than before the operation. His formerly pale complexion became pink and healthy. His farsightedness had improved so that weaker glasses have been prescribed by the eye specialist. His hair was growing more rapidly. His digestion was better than last year. He remained sexually distinctly improved. His weight and blood pressure remained normal.

The result was positive (considering that this man, who was not at all inclined to be enthusiastic, was so firmly convinced of the great benefits he derived from the operation, I regard him one of the most successful cases where a real "prolongation of efficiency" and a real "retardation of age" has been accomplished, not only temporarily but more pronounced in the second than in the first year after the operation).

Case LVIII.—Physician, aged sixty-two. He had had a general decline for the last eight years. Lack of ambition, memory failing. Frequent indigestion. A diagnosis of incipient senility was made.

September, 1923, a bilateral operation was done. Last report written December, 1924 (fifteen months after operation), "first benefits felt six months after operation. Slight increase of weight and physical strength and endurance. Digestion better, hair getting gray slower than before the operation, skin less wrinkled, no change in memory but slight increase in ambition and power of endurance. General outlook on life somewhat brighter than before. Pain due to muscular rheumatism considerably less, also 'epigastric distress' improved."

Considering the fact that this patient was a well observing physician I have given his report in more detail. He concludes as follows: "In my opinion it is an operation with no disadvantages (no ill effects whatsoever) and a good many advantages. (The beneficial effects are quite distinct and numerous.) Thus every man between fifty-five and seventy or even older, who begins to feel old age creeping on, should not hesitate to have it done."

Case LX.—Veterinary surgeon, aged sixty-nine. There was a general decline, especially in memory and sexual ability for the last three years. Had been losing weight steadily (had weighed two hundred pounds). For one year frequent urination and also frequent headaches. On two examinations, on October, 1923, and October 9, 1923, his blood pressure was between 200 and 250 systolic and between 100 and 130 diastolic. Pulse 80. Weight 166½ pounds. Prostate small, hardened. A diagnosis of incipient senility, with hypertension, was made. October, 1923, a unilateral operation was done.

December, 1923 (two months after operation), better sense of wellbeing, more energy, less languid. Patient had a serious accident falling down a long flight of stairs five weeks ago and had an attack of influenza afterwards. Asserts that he recovered unusually quickly. His headaches have disappeared. His frequent urination has improved. Weight 168¼ pounds. Blood pressure 190/100.

May, 1925 (one and a half years after operation), patient had further improved. He had no complaints. His digestion was better. Also his memory to a certain extent. He had been much more active which probably accounts for his slightly lower weight, 164 pounds. Blood pressure 190/100. Although his sexual ability was not markedly improved, he felt more confident in this respect and intends to get married. (In cases like this, I consider it imperative to impress very strongly on the patient the necessity of refraining from sexual exertions. In this case a second vasoligation on the other side should be considered in the near future.)

Case LXIV.—Physician, aged sixty-six. There had been a general decline of strength, memory, and especially sexual ability. Gradual loss of weight. Examination generally negative. Blood pressure 118/85. Pulse 82. Weight 177 pounds. Urine contained faint trace of albumen and occasional hyaline casts. Hemoglobin 70 per cent. A diagnosis of incipient senility was made. November, 1923, unilateral operation. A large hydrocele was operated upon at the same time (Volkman operation).

April, 1924 (five months after operation), subjective improvement. Physically stronger and decidedly more energy. No sexual improvement. Blood pressure 120/80. Weight 184½ pounds. Hemoglobin 80 per cent.

October, 1924 (eleven months after operation), patient has remained generally well, but his psychic harmony was greatly disturbed by discontent and worries. No further improvement. Weight 178½ pounds. Blood pressure the same. Result doubtful.

Case LXVI.—College professor, aged fifty-four. There had been a general decline for the last two years. Pronounced loss of energy, mentally as well as physically. Since a few months, urination at night. Sexual vitality always low. Further decline of libido and erections recently. General mental depression. The diagnosis was asthenia, premature senility. December, 1923, a bilateral operation was done.

January, 1924 (six weeks after operation), felt generally somewhat more energetic. Weight 127½ pounds. No distinct changes on physical examination.

December, 1924 (one year after operation), no changes. Suffering from a lack of energy and endurance. Had frequent headaches and is pretty badly depressed. An enlarged prostate had been diagnosed by his physician and since massage had no effect, he

considers x ray treatment or removal. He had kept his weight. His complexion was said to be much improved. Blood pressure had remained low. This was a negative result. (The failure in this case is difficult to explain, especially since no late reexamination could be performed and cases like this usually give a good prognosis.)

CASE LXVIII.—Accountant, aged forty-five. A general decline for about one year. Lack of endurance and energy. Gradual loss of weight. General depression. Extremely irritable. Diffuse rheumatic pains. Distinct sexual decline in libido, as well as erections. Somewhat premature ejaculations. Poor sleep. Blood pressure 160/100. Pulse 80. Weight 170½ pounds. Skin reaction very faintly red, almost absent. Prostate somewhat large. The diagnosis was premature senility. January, 1924, a unilateral operation was performed.

February, 1924 (five weeks after operation), patient was in buoyant spirit. Generally much better. Unusual appetite. Better sleep. Blood pressure 130, 95. Pulse 80. Weight 179 pounds. Skin reaction distinctly red.

December, 1924 (eleven months after operation), physical and mental strength and endurance greatly improved. Ambition and general outlook on life better. Depression gone. Sexual desire and ability slightly improved. Freer tendency for perspiration. Possibly more hair on body and arms. Patient writes, "I can stand any amount of work, mental or physical."

(This case is extremely instructive as compared to the negative Case 66. While the former one is of a distinct psychopathic nature with a prevailing adrenal constitution, this patient is of a very conservative, well balanced mentality and thyroidal constitution.)

(*To be continued*)

Comparative Studies in the Treatment of Chronic Ulcerative Tuberculosis of the Lungs*

WALTON FOREST DUTTON, M.D.

Amarillo, Texas

In modern textbooks on the practice of medicine, comparative studies in the treatment of pulmonary tuberculosis are conspicuous by their absence. They agree as to prophylaxis, sanatorium treatment, climatic treatment, home treatment, heliotherapy, artificial pneumothorax and routine medical treatment of the disease, its symptoms and complications.

It appears reasonable that in order to form a correct judgment in regard to the necessity for a certain line of treatment, it is essential to make a comparative study of treatment now available and contrast it with established routine.

PRESENT STATUS

Rest, good food, fresh air and proper medical treatment are the same the world over, it matters not whether the patient is in the Swiss Alps, the high altitudes of Colorado, the medium altitude of the Adirondacks, or the pine lowlands of New Jersey.

Volumes have been written on the treatment of pulmonary tuberculosis, but few give comparative studies to substantiate their assertions.

Is there no valuable lesson for the medical profession in an admission of these delinquencies? Tuberculosis claims its many victims—men, women and children.

Can we not bring to this problem the same methods so successfully employed in big business? The experience of the ages is now being drawn upon in the fight against this disease, but the means are entirely inadequate as shown by the continued ravishment of the disease. Too often, in default of exact knowledge, we blindly seek remedial agencies. The announcement in the lay or medical press of the discovery in Germany, in Sweden, in France, in England, or in the United States of an antitoxin, vaccine, serum, or chemotherapeutic agent for the cure of tuberculosis carries an evanescent ray of hope to hundreds of thousands. Physicians, ever alert for a specific, are none the less gullible.

ECONOMIC EVALUATION

Diseases like tuberculosis which kill in young adult life impose a heavier economic burden than those which affect infants or old people, says the Nation's Health for February, 1925. During the first two decades the family and the community make their investment; during the following forty years they reap the profit. * * On the basis of economic cost, tuberculosis leads, accounting for twenty-two per cent. of the total economic burden of disease.

The annual drug bill of persons suffering from some form of pulmonary disease is approximately one hundred and twenty-five million dollars, of which amount seventy-five million dollars is spent for so-called patent medicines.

The number of medicaments is increasing at a tremendous rate, beyond all proportion to the amount of systematic research being devoted to the subject. The frailties and suffering of tuberculous patients are being grossly exploited.

FUNDAMENTAL SCIENCES

It is true that the bacteriologist and pathologist have accomplished wonders in the present and the last generations in tracing the living carriers of the great infectious diseases and the world owes our Virchows, Pasteurs, Behrings, Flexners and many other valiant workers with these deadly carriers of disease a debt of eternal gratitude. But the fact is that the bacteriologist and pathologist have definitely reached the

point where they must turn to the fundamental sciences for the solution of many of their most important problems. To illustrate: Their antitoxins, their most powerful weapons in combating invading germs, are chemical substances of specific curative power but of unknown composition and never isolated as yet as pure principles. They are always injected into the body in the form of crude mixtures, loaded down with undesirable and to some extent harmful mixtures.

SPECIFICS

The isolation of the pure principles by chemical methods, supplementing the pioneer work of the bacteriologist and pathologist would prove one of the greatest advances in this work. The matter of health is closely bound up in the delicate adjustment of speed of the various chemical reactions taking place in the body. These reactions may be accelerated or retarded by minute quantities of enzymes. Water which constitutes more than three fourths of the body

contents, has a high dielectric capacity. This property of water is responsible for the ionization of the infinite numbers of molecules which water holds in suspension or in solution. Water is also one of the most important catalysts.

The advances by physical chemists in the study of colloids have found as yet but imperfect applications to the problems of the body, wherein nerve and cell, muscles and organs, the questions to be dealt in are largely those of colloidal chemistry.

Electrolytic solutions and colloids which make up the bulk of the body are especially adapted to electrochemical processes. Hydrogen ions permeate all living organisms. The slightest change in the hydrogen ion concentration fundmentally alters the organism, and hydrogen ions are of the highest electrical significance.

Carbohydrates are the source of the hydrogen ions which are released by oxidation. Lipoid films of the highest electrical significance are the exquisitely thin oil films which surround each of the trillions of cells which compose the body.

FUNDAMENTAL RESEARCH

These complex problems are too infinitely complicated to be solved by one class of scientists. Preeminently chemical in nature, the chemist alone is imperfectly equipped to carry them to a complete and successful solution. He must join hands with the pathologist, the experimental biologist, and the internist. Few institutions encourage such cooperation, yet only cooperation under ideal conditions of time and equipment will consummate the prosecution of fundamental research.

In order to establish a more perfect control over my problems, I have, during the past fifteen years, carried on comparative studies in fundamental research. This has provided a means of arriving at definite conclusions. The results of this work will doubtless be the elimination of many ineffective medicaments and much unreliable medical data.

I have selected for this paper a series of virtually uncomplicated cases which represent comparative chemicomedical research in the treatment of chronic ulcerative tuberculosis of the lungs during a four months' period.

Tables 1, 2, 3 and 4 show an average gain of two, 5.7, 7.4 and 13.1 pounds respectively. The selections as to height, weight, age, sex and other data were not arbitrary, but taken from the usual run of cases. Influenza as a probable predisposing factor in this series is worthy of consideration. The data relative to duration of infection and previous treatment is of little deductive value.

A matter of much importance, however, is the method of treatment. Medication was administered intravenously under strict supervision as to technic and scientific application.

Sweany, in a recent article (1) avers that tuberculins, chemicals, drugs, etc., have been void of results to date. In his experience no chemical or drug outside of food products will modify the disease process *per se*.

I cannot say that my experience coincides with this statement as shown by the above tables. These, it may be said, are a fair estimate of my work during a period of fifteen years.

COMMENT

In order better to understand the therapy in a particular disease at various periods of its development, one should attempt to correlate its phases of diminished and increased resistance with the altered powers of reaction of the tissues and their associated cells. The relation of a therapeutic agent to inflammatory reactions is determined by the tissues themselves. Future investigations will have to deal with the rôle played by the effect of therapy in altering the resistance of the tissues to the infective agent. That is to say, therapy must be capable of producing a state of immunity in human beings through the injection of quantitatively or qualitatively immunizing material. This of necessity demands a brief résumé of the newer pathological anatomical investigations. Ghon (2) has tried to correlate the primary effect of phthisis on the basis of combined clinical and pathologic histological observations in the further development of tuberculosis. The concept begins with the primary infection and continues through the period of generalization to the tertiary period. According to this authority chronic pulmonary phthisis represents no other than the tertiary stage of the infection, in which the further extension of the process becomes restrained on account of the previously intervening increased resistance of the individual and only slowly affects the involved organ through tubular invasion. Thus is found an analogue in its comparison with syphilis.

For the origin of chronic pulmonary tuberculosis, a new infection, a sort of reinfection in an already immunized body, is conceived. The reinfection, in contrast to the primary infection, may be multiple. A certain degree of anaphylaxis or immunization has been established. This again presents a particular phase in which the tissues should react characteristically to therapeutic measures. When the condition is no longer limited to the nodes corresponding to the primary focus, but embraces the diffuse swelling and caseation of tracheobronchial lymph nodes, which break and the virus is liberated into the blood stream. Therapeutic effort to be effective should participate in the reaction during this period of generalization. The degree of immunity produced depends in part on the time of life during which the primary infection occurs, the period of its generalization and the virulence of the virus.

Another factor of distinct importance is the extent of blood invasion. Tremendous blood invasion is an expression of diminished immunity. One deals here with a relatively rapid dissemination through the blood stream of comparatively large masses of the infectious agent, in a body more or less immunized, but the generalization decreases this resistance in direct proportion.

In this tertiary stage of chronic pulmonary phthisis, one has to deal not alone with a hematogenous metastasis, but a possible chronic organic phthisis. The amount of acquired resistance of the individual, the quality and quantity of the virus, the general state of nutrition, intercurrent infections like influenza or pneumonia, and pregnancy, are important factors in determining the course of the disease.

The chronic cases of pulmonary phthisis with a definite tendency to healing through the formation of hyalinized fibrous tissue in the individual foci, are

favorably influenced by physical therapy, and general supportive measures.

When one deals with cases in which the characteristic exudative reaction is mostly in evidence, encapsulation and healing meet with difficulties. The exudative reaction is a sign of lowered resistance, a rapid progressive destruction of the organism. Here physical therapy fails, or may hasten the destructive processes. For this reason we stand face to face with new problems in the therapy of chronic pulmonary tuberculosis. Irrespective of the prophylaxis relative to primary infection and reinfection, we must consider our present methods. It remains for us to evaluate chronic pulmonary phthisis from the point of view of its genesis, prophylaxis and therapeusis, that future generations may be insured of absolute immunity against this disease.

CONCLUSIONS

1. A comparative study of the therapeutic value of drugs in disease is worthy of consideration.
2. The studies made in this series of cases have proved of practical value.
3. The administration of arsenic, iron and nuclein intravenously in these cases was beneficial.
4. In cases presenting clinical evidence of chronic ulcerative tuberculosis of the lungs, these remedies given by the blood stream produce a greater degree of increased resistance and immunity.

(*Concluded from page* 440)

THE SPLEEN

Incidence 2.1 per cent. (Dévé). Eighteen North American cases have been reported to date.

The question of splenectomy versus the closed method or marsupialization and drainage in the case of this organ is still *sub judice,* with the battle leaning towards splenectomy. The question here is not on all fours with that obtaining in hydatid cysts of the liver. The spleen is an organ which can be easily dispensed with in man.

Multiple hydatid cysts of the spleen are not uncommon, and can be easily overlooked. There is here, of course, no question of infective cholerrhagia, and the closed method should, therefore, promise even better results than in the case of liver cysts. Splenic cysts, however, by the time they are diagnosed are often of enormous size, and extremely adherent. Moreover, if subsequent splenectomy prove necessary, and it often is, the adhesions consequent on the adoption of the closed method might complicate further treatment. As a matter of fact, the closed method has not been so generally adopted in the case of splenic cysts as in the case of liver cysts, though Lagos Garcia reported five cases in children so treated, and the tendency has been, especially in France, to favor primary splenectomy. Prolonged drainage and postoperative hernia have been especially frequent after marsupialization of hydatid cysts of the spleen. I have dealt with this subject *in extenso* elsewhere.

MUSCLES AND CONNECTIVE TISSUE

Incidence 5.2 per cent. in adults, 3.2 per cent. in children (Dévé, 1918).

Hydatid cysts of the neck have been reported by Ramsay, Verdelet, Nogueras, Marsiglia, Baccarini, Bevers, and Blacksley. Guterback collected twenty-six cases in 1893. Hydatid cysts specifically in the sternomastoid muscles have been reported by Guyot and Jeanneney, de la Mata, Rosso, and others; in the iliopsoas muscle by Caldera; in the buttock by Ritchie, Hutchings and Cavenagh; in the thigh by Lombard, and Rollet of France, and Da Costa in this country; in the erector spinæ muscles by Lasserre and Laney, who reported three cases in 1923, and collected twenty-six others. Loubat and Lartigaut, and Kothary have reported hydatid cysts of the muscles and connective tissue of the back. Petrescu of Roumania, and J. Ramsay of Australia, report cases of hydatid cysts in the axilla, and Joannides and Riley an American case in the scapular region. A case of hydatid cysts in Scarpa's triangle was reported by de la Mata in 1923, and a unique case of primary hydatid cyst of the ischiorectal fossa by Vergnory, Morel and Vachey.

Cysts in the abdominal wall also occur, and have been reported by Lenormant, who cites sixteen cases collected by Marguet and five cases of preperitoneal cysts collected by Gorse of Lyon. The interest in these cases is mainly a diagnostic one, and in this connection desmoids of the abdominal wall must be remembered. De Tommasi, Vergano, Laurenti, Gowland, Romano, and others have also reported cysts in this location.

It is here that excision en masse is the ideal treatment when practicable. Formolage should always be done. It must be remembered, however, that the condition is rarely diagnosed before operation, except in localities (e. g., South America and Australia) where the disease is so common that it is always borne in mind. As a matter of fact, marsupialization and drainage is the treatment which has usually been adopted.

THE PERITONEAL CAVITY

It cannot be too strongly stressed that while primary hydatid cysts of the peritoneal cavity do obtain, in the immense majority of cases they are secondary

to the rupture of a primary cyst of the liver or spleen. And this although it may be difficult even at autopsy to find evidence of said primary cyst, which may be represented by an insignificant scar only. A further point to be remembered also is that the interests of a patient, in these cases, are conserved by not doing too much at one time. It is much better to attack this condition, always a serious one, in several stages, not forgetting the primary focus, if the latter is still active (Dévé). One has only to read such cases as that reported by Cullingworth and Clutton to realize what can be done by taking—in their case—"eighteen bites at a cherry": and such cases could be multiplied ad infinitum. Thus, Deniker states that six or eight operations are often necessary, and Abadie, Feyguine and Abadie write that repeated operations may cure apparently hopeless cases: De Arias and Arrizabalaga concur. In Flandin's case, six operations were performed in twenty-four years.

I must not leave this subject without drawing attention to the fact that most of the socalled cases of retroperitoneal cysts are, in reality, in the first place cases of secondary intraperitoneal echinococcosis, which have become secondarily encysted. Here, too, then, one must look out for the primary focus. Brumpt says: "Cysts of many kinds become subserous when they fall into the abdominal cavity (the cysts of the Tænia serrata, cysticercus pisiformis; and of the Tænia marginata, cysticercus tenuicollis). Moreover, the fact has been experimentally demonstrated in the matter of peritoneal grafts." Guibé writes: "Engrafted hydatid cysts rapidly acquite an endothelial covering, and they become secondarily extraperitoneal": Blanchard concurs.

PELVIS

As regards pelvic cysts, the chief danger comes from backpressure on the ureters (Deming, Covisa, etc.). Deming, of Connecticut, reported one case and collected forty-seven others from literature, in which complete urinary obstruction obtained. Operative mortality 34.1 per cent. Again, many cases reported as being primary hydatid cysts of the pelvic organs (uterus, ovaries, prostate) are, in reality, cases of secondary intraperitoneal cysts, which have barged into and become incorporated with the organs mentioned: this fact indicates conservatism, when possible, in their surgical treatment. It is necessary to insist that secondary cysts of the pelvis are not necessarily accompanied by peritoneal cysts elsewhere. The latter may be extremely discreet, thus, there were only four in Dévé's case; three in the cases of Dumont and Ahumada; and only one in the cases of Leudet, Toupet and Walther. There is nothing strange in this, for one may inject say two hundred thousand scolices into the peritoneum of a rabbit, and discover at autopsy that only a few cysts have developed: most of the hydatic germs having been destroyed—pseudotubercular echinococcosis. The same remark applies to man, whose coefficient of resistance varies as much as that of animals.

Primary pelvic cysts do occur, but they are very rare, about a dozen to date (Dévé, 1924).

Marion reported one case cured by suprapubic operation. Franc says: "Tuffier and Villar operate from above, marsupialization may be necessary because of adhesions." He quotes Veau and Mauclaire to the effect that extirpation is ideal when possible. Fiolle lauds the coccyperineal approach for retrovesical hydatid cysts. This route was designed for extirpation of the vesicules seminales, and has been advocated by Cúneo for ablation of ampullary rectal cancer. It is also useful for prostatic and rectosigmoid work. The name was originally given by Demarest.

1. *Uncomplicated pelvic cysts.*—Dévé remarks that there are two surgical routes; the upper, peritoneal, represented by laparotomy: and the lower, extraperitoneal, comprising the vaginal route in women, and the perineal route in men. He selects the upper route:

1. To determine whether the lesion is primary or secondary.
2. To ascertain the size and number of cysts.
3. In order to practice integral ablation, because such an operation permits immediate closure without drainage.

He stresses the fact that formolage should always be used, and if there has been soiling of the operative field, it should be swabbed with ether. In this opinion Lhuillier, Ahumada, Caviglia, and Belaustegui concur.

With Chueco, colpotomy is an obsession, but in this he is practically alone.

The various procedures are: enucleation, decortication, extirpation, marsupialization and drainage, and the closed method. One may add formolage *in situ* in the case of multiple small sessile cysts.

The first two are mentioned only to be condemned, and the third is rarely feasible.

Enucleation consists in the extraction of the mother cyst intact from the adventitious capsule, as suggested by Posadas for small cysts of the liver. It has been employed by Peyrot. Picqué and Gregoire reported a brilliant success by this method. It is, however, an unnecessarily dangerous procedure, and it is much wiser to practice extraction of the mother cyst after puncture and formolage.

Decortication is equally dangerous, and useless. It consists of dissecting out the cyst en bloc, like a tumor (Veau). Passeron, Tribaudeau, and Soubeyran tried it, and were stopped by violent hemorrhage. Albarran employed it, but opened both the bladder and peritoneum, as also did Trofimoff. Bonneau all but entered the rectum, and in Meyer's case, death occurred in twenty-four hours from peritonitis as the result of perforation of the rectum. There is also danger of reinsemination of the pelvis. Salvador, Boero, Lejars, Quénu, Routier and Sieur concur. It is wholly bad.

Marsupialization and drainage has nowadays given place to the closed method. Even in the case of multivesicular cysts it is no longer fashionable, providing that the sac is thoroughly cleaned out, and use made of formolage and ether.

Reduction without drainage, after formolage, is at the present day the operation of choice.

2. *Complicated pelvic cysts.*—Drainage is practically always necessary in these cases, and here come in the various extraperitoneal routes, colpotomy in the case of women, and Fiolle's technic in the case of men. The upper route is indicated in the cases of cysts opening into the bladder. Guyot uses a perineal counter opening. Bentley Squier closes the

vesical opening, and drains through a prerectal incision.

For hydatid cysts complicating pregnancy, we have the choice of Cæsarean section or vaginal puncture, in the latter case preceded by formolage. On no consideration should an attempt be made to push such tumors up out of the pelvis, as they are usually fixed, and always fragile. A second operation will be necessary after the puerperium.

THE BONES

Incidence one per cent. One American case has been reported (Walker and Cummins) since Lyon's statistics, which contained two.

The salient point to be remembered in this connection is the close resemblance assumed in this location to the rare echinococcosis alveolaris. Generally speaking, thorough curettement and swabbing with formalin or ether (some surgeons use the actual cautery) may suffice in cases diagnosed early—a rare event: while in late cases, wide resection with possible subsequent bone grafting, or amputation will be indicated.

In the case of the pelvis it is luckily usually a question of the iliac wing, of which the technical resection is easy, and generally well supported by the patient (vide case of Buzzi, cure in two and a half years: case of Finochietto, cure in four and a half years). If the coxofemoral articulation is invaded, resection is necessary, and the prognosis naturally poorer.

If the disease is still more diffuse, involving half of the coxal bone, with an enormous abscess of the soft parts, the outlook is practically hopeless. Simple incision of the abscess, with extraction of the sequestræ and drainage, results sooner or later in one hundred per cent. mortality from fever, cachexia, etc.; on the other hand, the interilioabdominal disarticulation kills equally surely from shock (Desplas, Boppe, and Bertrand).

Other recent reports in this connection are those of Gerand and Mignot, Mignon, Costantini and Duboucher, and Costantini of France: A. Lesi of Italy: Roldan of Uruguay: A. S. Joske, H. Harris, Corlette of Australia: A. Stolz of Germany: Neumann of Poland: Zorraquin and Gomez, A. Buzzi of Argentina: and Cholmeley of Great Britain.

Hydatid cysts of the spine have been reported by de la Mata of Spain: Fournier of Uruguay; Connell, Syme, and Gill and Bullock of Australia: Sholkoff of Russia; Guleka, and Boge of Germany: Tytler and Williamson, Owen, Theobalds, Rendle, and Colman of England. Kersente of Algiers (1924) points out that they are rare, only forty-two operative cases appearing in literature, of these only seven were cured; the prognosis is very bad. Palliative treatment (laminectomy, curettage, and formolage) is usually alone possible.

In Sholkoff's case, resection of the spinal ligaments was found necessary. The closed method was adopted, which is open to criticism, as the cyst contained hundreds of daughter cysts: suppuration occurred.

In Gill and Bullock's case, primary hydatid cyst of the body of the second lumbar vertebra with daughter cysts in the lumbar muscles and spinal canal, a wide laminectomy followed by drainage for twenty-four hours was done. Results excellent, but here operation was done within three months of the first symptom.

Tytler and Williamson report the removal of fifteen extradural cysts for compression myelitis in the dorsal region in their patient. The end results were good. They note that the location is usually posterior (Maguire).

Owen of Melbourne reported five operative cases, site extradural: the closed method was adopted in all except one instance, case three, which was drained: the wound closed in four months. Results good in every case.

Colman of St. Thomas's Hospital, in 1899, reported a personal postmortem extradural case in a boy aged ten, and reviewed the whole subject, going back to 1807. In twenty out of twenty-four collected cases, the cysts were extradural, and the site dorsal in ten out of twenty-five cases.

RARER LOCATIONS

Little need be said as to the surgical technic to be employed when dealing with hydatid cysts of the rarer locations. Cases have been reported in the breast (LaConte, two American cases; Etchevaria; Ramsay): thyroid (Henle collected eighteen, and Vitrac twenty-one): pancreas (Albo of Uruguay; Peters, Phillips, and Ashton in North America): stomach (Delore and Croizier, Savariaud, Brumpt): appendix (Trinca): nasal septum (Lyon's case 165): tongue, gums, mouth, pharynx, parotid (E. Pieper): larynx (Schussler, cited by E. Pieper): skin (ibid.): mediastinum (ibid.): palm of the hand (Maug, cited by Cobbold, p. 281): orbit (Kramer collected sixty-eight and Golowin ninety-three observations: cases have also been reported by Solares, Rudolph, Cabaut, Tiscornia, Stuart, Evers, Lawford, Griffith, Werner, Marshall, DuToit, Satanowsky, O'Hara and in America by Lyon, case 131): placenta (cited by Cobbold, p. 276): kidney of a fetus (Oesterlin, cited by Cobbold, p. 459).

Such cysts must be treated on general surgical principles. Generally speaking, excision is the ideal treatment: if this is impracticable, the closed method should be selected in clean cases (Vegas so treated all his thyroid and pancreas cases), and marsupialization reserved for complex cysts. Formolage is always indicated. It must be remembered, however, that the majority of such cysts, except when occurring in countries where the disease is rife, are seldom diagnosed before operation.

Hydatid cysts of the heart have never been diagnosed during life, and as most of them have been found in the intraventricular septum, it seems unlikely that they will ever become amenable to surgery. Cysts of the anterior ventricular wall, or of the pericardium, however, might possibly be treated by the Posadas method (Vegas and Cranwell). I have dealt with hydatid cysts in this location quite fully elsewhere.

Finally, it is a matter of interest to note that hydatid cysts have been found in almost every organ of the human body—with the single exception of the testicle: my authority is Bland-Sutton.

A very comprehensive bibliography on the subject of echinococcosis will be included in the author's reprints.

The Health Examination and Its Distinctive Features*

C. WARD CRAMPTON, M.D.
New York

A new field is opening for the physician. I venture to predict that in the future, all intelligent men and women will have their own health physician to whom they will look to keep them well and vigorous. This will not come until the public recognizes the fact that the physician can adequately give this service. To hasten the day and to insure its coming, we shall be wise to address ourselves to the task of becoming as efficient and successful in this field as in the field of prevention of communicable illness and the cure of disease.

While the difference between the health examination and the usual office call, which may properly be called disease examination, seems so little to those who are approaching the subject for the first time, study and experience will reveal distinctive features of great importance. Indeed the success of the health examination depends wholly upon making it widely different from the customary search for disease, although this search for evident pathology constitutes one of the several parts of the health examination.

At the outset, I propose the name of health client for the candidate for the health examination, dispensing with the customary term patient. The health client comes to the physician not to be relieved of a pain, but to be foreguarded against it. He is impelled by wisdom, counselled by caution. He wishes to live long and keep well. Sometimes he is wise enough to know that there is a degree of health superior to the average. He desires optimum health. To satisfy this man, we must not cling to the old idea that one is "all right" if no disease can be found which is mentioned in the medical dictionary. Health is something positive. It is not merely absence from disease. The patient may be free from discoverable pathology and yet a poor specimen of manhood, leading an unhygienic life and headed toward trouble. He may have no disease, yet he has no stock of positive health. His margin is zero.

To increase this health margin, to develop an inferior physique to reasonable strength, to attain maximum efficiency, to increase personal capacity for happiness and work, to lengthen the span of life and health, are the purposes of the health examination.

Here is a new subject—health. Hitherto, practically all of our medical books and even the books on hygiene treat almost exclusively of disease and its prevention. We need more textbooks for the physician on the subject of *positive* health and how to prescribe it.

The health examination differs thus far from the ordinary disease examination in the name of the one examined, who is a health client—in the motive which brings him to the office, and in the objective, which is positive health. Yet to a great degree, it is true that every health examination must also be an investigation for disease. This is the part with which the physician in his ordinary practice is familiar. In the health examination, evidences of disease must be discovered, preclinical signs disclosed, and tendencies which may later cause disease carefully searched for.

The scope of the health examination is extensive. It covers the whole man—his past and present, and seeks to recast his future in a larger mold. The usual examination is intensive, seeking a clear definition of the pathological condition. The health examination, therefore, consumes more time, requires a broader vision, and a wider and greater scope.

The health examination has four fields: 1. Heredity and collaterals. 2. Habits and hazards of life. 3. Diseases—past, present and future. 4. Prescription and instruction of client.

A STUDY OF HEREDITY

Large values can be obtained from a rapid and well directed study of the family tree. One oak leaf will differ greatly from the others, although they are all oak leaves (subject to gall fly attacks, but invulnerable to various rusts and blights), their immunities and susceptibilities are heritable, though the diseases themselves are not. We need more Mendelism in medicine. Ontogeny and phylogeny recapitulate each other. Many times the future can be foreshadowed in contemporaneous aging periods of his forbears. There is a probably greater family resemblance in kidney tubules than there is in noses, and a greater similarity in the efficiency and endurance of the pancreas than in stature.

In this study we must learn what is important to

*Address delivered at a special meeting of the Medical Society of the County of New York as the report of the chairman of the subcommittee on the instruction of the physician relative to health examinations.

our client's future, and what is merely incidental. A small matter may completely change the whole tenor of our instruction. Moreover, we must devise and adopt a method of routine that will be inclusive, decisive, and swift. If we can afford to conduct health examinations in our practice at all, these and other phases of the work must be made efficiently systematic.

To this end it is of greatest advantage to provide the client with a personal history questionnaire, which he can take home and fill out at his leisure. For this purpose the ordinary blank will not serve. It must sympathetically be adapted to this need. This saves time and a better record is obtained. It must not supplant the further questioning by the physician in the office, with which it in no wise interferes. It is an indispensable basis for further records and renders it possible to complete the examination in a reasonable period of time. It is often convenient for the client to have his examination in two office calls, the first for history tests and physical examination, the second when the laboratory reports are in hand for check up prescriptions and instructions.

HABITS AND HAZARDS OF LIFE

Men and women are guided in the conduct of their lives mainly by instinct. They eat, work and sleep as their heredity and circumstances command. Surrounded by conditions that greatly differ from those which determined their present structure and the character of their instincts, they suffer from the results of inappropriate reactions and maladjustments. These are repeated daily, slowly cause deterioration and disease. Diet, exercise, recreation, rest and work may either make or break a man. It is our purpose to enhance health, happiness and efficiency, and to prevent damage. To search the daily life thoroughly takes long, well directed, effort. Here the questionnaire saves time and adds completeness and accuracy. Always, however, the salient points which stand out in the history will require more complete notation, which can be rapidly and incisively done.

Since our prescription is to be given in the form of life guidance, and not but incidentally in the form of medicine, these data are of paramount importance. They will also serve to arouse the physician's suspicion of pathology and to guide his search for symptoms and preclinical signs.

PERSONAL HISTORY OF DISEASE

The questionnaire should be especially complete and simple in the matter of previous diseases of the health client, and in the record of such minor symptoms and discomforts as most men occasionally experience. This information, with the heredity record, points the search for pathology toward suspected points. Previous disease affects the future in several ways:

1. It often leaves a mark, scar or effect in the organ affected, which may subsequently flare up into another attack.
2. It may leave a half cured focus of infection which continues to cripple the organ and damage the whole body.
3. On the contrary it may confer an immunity.
4. It may have created a weakness in another organ which in later years determines a different but definite disease.
5. It may damage the whole body and lead to earlier deterioration.

In the ordinary examination of the patient in the office we are definitely concerned with an incisive search for the cause of the disease or disability present. In this phase of the health examination, we are searching a wide field for influences that will mar the future. Of course there is nothing to prevent the scrupulous physician from extending the boundaries of his usual inquiry beyond the confines of the immediate disability of his patient. In fact it is becoming good practice.

DISCOVERABLE DISEASE

The health examination also includes a search for disease which may be present, but yet unsuspected by the health client. This is the field with which the general practitioner is more at home. Yet it will require a distinct effort for the busy family doctor, who customarily spends ninety per cent. of his time visiting sick beds, to bring himself to search for signs of disease which may be present in an apparently healthy man who has come into the office. It is only after considerable experience that one becomes accustomed to the sense of a need of effort which this search necessarily entails. In fact this has been so far outside the experience of some physicians that health clients coming for an examination, have been disappointed. This part of the examination will be easier for those who have been in the habit of treating chronic and constitutional diseases, and most difficult for the highly expert specialist and the overworked family doctor.

PRECLINICAL SIGNS OF DISEASE

This is a new term in medicine and needs definition. I suggest that the term be applied to signs which foreshadow disease and precede subjective symptoms. With many of these we are familiar. The hardening of the arteries, the appearance of albumin in the urine, the Romberg symptom, are examples, but there are in addition a multitude of half known or little defined preclinical signs which are not often to be found in textbooks, but which have been noted by thoughtful physicians who have followed their clients for a number of years and have seen the gradual development of constitutional diseases. Some of these occur first as minor discomforts, irregularities in function and unnoticed disabilities. The condition of the skin, the background of the eye, the nature of the first sound of the heart, the efficiency of vasotonicity and gastrointestinal tonicity are particularly fruitful fields for investigation. It is in this department—preclinical medicine—that lies the greatest opportunity for development. Herein lies certainly the greatest need of the public, for who can witness the enormous increase in the number of deaths from disease in the cardiovascular renal triad without being thoroughly convinced of the existence of a great opportunity for advance and a vast need for medical service?

It is in this field that the public has already been educated to apply for relief in the form of the health examination, and if they are to apply to the practising physician instead of to health organizations and more or less regular practitioners, it is incumbent upon those who constitute the rank and file of organized medicine effectively to reinforce their ability to meet the situation.

DEFICIENCIES IN THE STRUCTURE OF THE BODY

The anatomical structure of a man is both historical and prophetic. It reveals signs of his successful struggle against disease, and shows the cost of his victories. Weakness, past, present and future, is revealed by a flattened chest and a lax protruding abdomen, and constitute a challenge to the constructive ability of the physician.

In the health examination the tape measure is a necessity. In the ordinary office call the physician may feel that there is little or no reason for a complete stripped examination. In the health examination it is essential.

FUNCTIONAL TESTS

An important characteristic of the health examination is the functional testing of the organic equipment. This is not customary in the usual office routine unless it is directly related to the pathology at hand. In every health examination a routine test of the motility and clearance of the intestinal tract, and one or more circulatory function tests are given, preferably blood, ptosis, and pulse recovery tests are given.

SUMMARY

With this information all in hand, the examination is completed. If the patient is then dismissed, however, the procedure is a failure and nothing results. The most important part is to follow.

It is now necessary for the physician to assemble his data and to determine the various factors which bear on the patient's future so that he may do two things. First, he must decide upon his own course of action, and secondly, he must lay out a program for his client and give him the necessary instructions.

He commonly finds obscure pathology which requires further diagnosis. He frequently discovers definite disease which needs medical treatment. This he may give himself, or he may refer his case (now a patient) to a colleague for special treatment.

He may observe preclinical signs which foreshadow disease and he will prescribe a régime which will postpone or prevent it. He will note errors in life management that have already done harm or will prejudice the future. These he will seek to remedy by sympathetic counsel. He will find structural and functional deficiencies and prescribe methods of improvement.

With many factors in hand, considerable judgment will be required to adopt a plan of action and dealing with the client so that just enough will be attempted and carried out in just the right way.

PRESCRIPTION AND INSTRUCTION

His course and program determined upon, he has the task of so instructing his client that the desired benefit will be obtained. This is by far the most important and critical part of the health examination. Without it all that has gone before is futile. Our prescriptions, however enlightened they may be, are of no avail unless they are faithfully followed. By some means, the client's effective continuing interest in his health must be aroused. The quickest and the most harmful way to do this is to frighten the client with warnings of danger. This is frequently unnecessary and destructive. The better way is to point out the benefits of a large positive health margin and make it continuingly worth while to adopt a well-directed mode of living. This requires skill, conviction, understanding and enthusiasm, and it is most effective when it is supported by the physician's own example of abundant health.

To aid this purpose, the client should be given his health prescription in written form. This is most effectively given in the form of a health booklet, which contains the carbon copy of the more objective of his tests and measurements, compare with the normal, his diet and exercise clearly set forth, and his own health questionnaire, which contains habit items in which he can improve. In this he also keeps the record of his progress and brings it back to his health consultant at the end of six months or a year for his reexamination. This clinches the whole matter in so far as it is possible to do so.

CONCLUSION

It will be seen, therefore, that the health examination is not a perfunctory fifteen minute survey, ending with the assurance that "You are all right. I would recommend you for any amount of insurance." It is an important event in the life of the client, and not less than an hour's hard, welldirected work on the part of the physician is required.

No one is qualified to do this work unless he is prepared to adopt a new point of view and to labor to acquire a breadth of knowledge in a field which is coextensive with all of life and medicine.

This is possibly a new specialty in medicine, but it is one in which the presentday specialist, though he may not enter it with ease, will play a most necessary part. The health specialist cannot hope to know all the special fields of medicine, as they may be severally known by his colleagues, expert in diagnosis and treatment in their various lines. To these he must refer his patient and to those he must look for instruction to be able to recognize the obscure and important preclinical signs of disease.

While we may rightfully acknowledge that this field has been prepared for us largely by others, and we recognize the fact that health service clinics in properly organized hospitals can and should aid those who cannot afford to pay the office fee, yet we feel that it is a part of the work of the medical profession, which can best be done by the private physician in his own office, where the personal, sympathetic relationship of health client and health consultant may be developed and maintained to the greatest advantage to all concerned.

Thus there is opening a new field for medical service. It awaits the physician who will faithfully prepare himself to discharge his full duty therein.

571 Park Avenue.

[Following Dr. Crampton's introduction, five papers on preclinical medicine will appear. The balance of the papers will come out in the two subsequent issues of the Medical Journal and Record. This symposium, held at the New York Academy of Medicine, should prove to be a solid cornerstone in a field of medicine hitherto not sufficiently stressed. We are sure you will look forward to this splendid array of material by the leaders in their respective fields of medicine, who will cover every branch of medicine from the preclinical point of view.

The Editors.]

The Genitourinary System*

EDWARD L. KEYES, M.D.
New York

The clinical picture we are called upon to contemplate in studying early physical signs of disease and early symptoms of disease is a picture which, if it deceives us at all, will deceive us into thinking that the person has nothing the matter with him. That is our difficulty; that is the difficulty we are trying to face today.

But generally speaking, the aspect of the patient is that of a healthy person. I have asked myself, "What is diagnosis? Why do I make so many faulty diagnoses and why do other people make so many faulty diagnoses?" Largely, of course, because of an insufficient physical examination, and that in my department, of course, immediately brings to mind Dr. Osler's well known adage that "One of the two functions of the consultant is to put his finger up the patient's rectum." I suppose that the lack of the habit of doing that brings a great deal of profit to the specialist in urinary diseases because other doctors will not casually and constantly make rectal examinations.

The second thing that comes to my mind is the most venerable and time honored and the most respected in the arts and all the customs of medicine, sometimes known as uromancy. Uromancy I think deserves the fame it achieved, meaning, prognosis by the inspection of urine. No one now looks at the urine of the patient. The urine is taken and bottled, and is then carefully carried, more or less surreptitiously, to the laboratory, encouraged to ferment there for some twenty-four hours, and then, lest the laboratory man see too much, he interposes various glasses between his eyes and the thing he looks at. So that we all get as far as possible from looking at the urine.

Now I, in my humble trade, learn more about urines by looking at them than I do by any other method. There are other things worth doing to urines, but above all else it is worth looking at the urine under various circumstances, but notably simply the urine as it is passed. It is more accurate still, perhaps for certain purposes, to look at the urine obtained by catheter under certain circumstances.

Just to look at the urine is a most marvelously helpful thing. Many of the patients who come to me for diagnosis suffer a lack of diagnosis in large part because no finger has been put up their rectum, and secondly, the urine has never been looked at by the human eye unprotected by microscopes or other implements. So that insufficient diagnosis depends, of course, largely upon insufficient physical examination, but it also depends, as we all know, upon lack of genius. The brilliant diagnostician is the genius who has a flair, almost that of a hound on the scent, for the essential symptom. In trying to analyze in my own mind what that means, I say to myself that perhaps our difficulty is largely that we attribute symptoms to diseases and not to physical facts. Diagnosis doesn't consist in saying, "The patient has a fever and therefore he has typhoid fever." The diagnosis consists in attributing the observed physical fact to an assumed—possibly provable, possibly not—physical cause.

I had a brilliant example of that only last week, where I first of all made an erroneous diagnosis, or at least partially erroneous, and then the following week I made a correct diagnosis. A patient was sent to me by a physician who had seen him through a socalled grippe, and following this the patient had been suffering from frequency and painful urination, and it was noted by his wife that his urine did not smell right. His urine did smell badly and also, when looked at with the glass, it had muddy pus in it. While he was convalescing from his grippe, he was sent to me for a cystoscopy. I examined him under unfortunate circumstances, so I came to a conclusion that he might have retention of urine. After he had passed his urine, I put a catheter in his bladder. He still had some urine in his bladder. He was a man of about sixty, so that I thought he had something the matter with his prostate. I used the cystoscope; found nothing the matter with his bladder or prostate, and as I found the patient was not particularly strong, I thought it wise not to catheterize the ureters at that time. I sent him home and instructed the physician to wash the patient's bladder out and give him urotropin. The physician reached the justifiable conclusion that he could have done all those things without sending him for a highbrow opinion to me. He protested that I hadn't catheterized the patient's ureters. I stated that the patient's condition wasn't propitious for that. I suggested that he send him back within a week and I would catheterize his ureters without additional charge. He came back to me and I catheterized his ureters last Monday and I obtained information that he had marked infection of his kidneys but not of his bladder. The infection was a curious one and I never had seen quite the like of it before. I sent the urine to the laboratory for culture and obtained an interesting report, that the patient had a paratyphoid bacillus in his urine. His grippe immediately becomes clear now. He had had paratyphoid; that was his grippe. He had a curiously inflamed bladder, and the entire situation I believe will clear up on urotropin and bladder washes.

I think that is a fair illustration of how one wobbles about until either genius or experience or the laboratory, or whatever gives us the hint, and the situation is clarified.

It seems to me that the way we get at earlier diagnosis, the way we get at preclinical signs in medicine, is by paying more attention to the striking symptoms around which gather groups of other symptoms. For instance, there is the clinical picture of tuberculosis. I suppose that it would have been highly profitable, when I was a young man, for a speaker on this rostrum to talk for an hour upon the

*Read as part of a symposium on the preclinical signs of disease, presented under the auspices of the Medical Society of the County of New York at the New York Academy of Medicine, January 15, 1925.

one fact, that a patient in youth, with unexplained frequent and painful urination, had tuberculosis of the kidney. I don't suppose it would be necessary to talk for an hour on that subject now. How do I know it? Because I don't see any more cases of tuberculosis of the kidney; the general surgeons manage those now; make their diagnosis. Twenty years ago, four out of five patients with kidney disease that I saw had tuberculosis. They came to me because somebody had been washing out the bladder for forty weeks and hadn't done them any good, and I sometimes found that the patient had tuberculosis. Spontaneous, frequent, and painful urination in a young person, whether or not accompanied by hematuria, is caused by tuberculosis. It is no longer considered a preclinical sign, but a perfectly definite clinical picture that everybody knows about.

In the matter of tuberculosis, the converse was the difficulty. These patients were brought to me not as having tuberculosis, because the laboratory didn't prove that they were cases of tuberculosis. There are two ways out of this dilemma: improve your laboratory technic and you will find tubercle bacilli more often; also improve your clinical and pathological knowledge; and you know that as mixed infection predominates in the older tuberculous conditions, the difficulty of finding the tubercle bacillus naturally becomes greater.

It is recognized that by other methods, such as the pyelogram, that it is possible to make a perfectly definite diagnosis of renal tuberculosis without the tubercle bacillus being found. That is a preclinical sign that has gone by.

There is a preclinical sign that is predominant over all other preclinical signs, as I see it in my practice nowadays, and that is the hematuria that is cured by swamproot or other infallible remedies.

I saw a patient today—he is on his way to the hospital now. I am going to cystoscope him and bail a lot of clots out of his bladder this afternoon. This should have been done five years ago when he had his first hematuria and the bleeding stopped, and he went along in perfect peace until he got his bladder full of clots and could not go on. Hematuria not accompanied by pyuria, of brief duration, or we might also add, occurring in an adult, is to be supposed an evidence of malignant tumor of bladder or kidney, until it is proved to be something else. That is really the greatest and most important clinical sign today, because we are in the matter of tumors just at the point where we were when I was a youngster.

Cancers today are just about where our tuberculoses were then, and with the various means, improved diagnosis, improved therapeusis, we are getting to a point where carcinoma of the urinary organs, like carcinoma elsewhere in the body, if it can only be gotten at early enough, is perfectly manageable.

I do not suppose it is so much the difficulty in the clinician here as it is in the patient. The patient has a hemorrhage and is prepared to die, and the hemorrhage is stopped, and the patient is prepared to run as far from a doctor as he possibly can—that perfectly natural instinct must be controlled just as much as though he had a pulmonary hemorrhage.

There are many other items that could be mentioned and I will mention a few of them, even at the risk of blurring the picture I would like to leave in your minds of what I have said.

There is a simple point in analyzing urines, which is overlooked by clinicians at large. The finding of casts is almost an essential. They might not be found in every specimen of urine examined, but surely you expect to find some sort of casts sooner or later. Yet a diagnosis may be made of surgical nephritis without any casts being found. I quite agree that the toxic nephritides, socalled medical nephritis, are characterized by the presence of casts in the urine. In part at least this is because the urines we have occasion to examine are so commonly befouled with more or less pus and blood, that it is slightly more difficult to find casts. I fancy if the other solid elements could be gotten out of the urine, the casts would be much more readily discovered. But we do make diagnoses without finding casts, and I have defied people to find casts in some of these cases and have had good laboratory men fail to do so. For some reason casts are less commonly found in the urines of patients who have nephritis as a result of surgical infection than is the case in toxic nephritis. Indeed, one of the tricks of the trade is to make a diagnosis of tuberculosis of the kidney where a patient has a good deal of pus and a variety of casts in the urine; the trick depending upon the fact that such a patient is likely to have a toxic tuberculous nephritis on one side, due to the infectious tuberculous bacillary, and a necrotic condition on the other side. You will have the tubercle bacilli on one side giving the pus and the toxic nephritis due to the tuberculosis on the other side giving the casts. I don't feel that one may quite make a diagnosis of tuberculosis of the kidney on that combination, but it is a striking combination when seen.

Another item of interest is the diagnosis of carcinoma of the prostate. Within this week I operated upon a patient with carcinoma of the prostate and have implanted seeds of radium into that prostate, with a fair hope of controlling that condition, or at least with a much better hope than I have ever had in any other case. How did it happen that I should have made a brilliant diagnosis early in this case of carcinoma of the prostate—so early that I feel that it is still well within the prostate and can perhaps be controlled? Largely because I didn't make the diagnosis; another man made it for me, so that I don't have to blush about it.

The diagnosis was made under these circumstances: This patient went to his physician, who is an expert in urology in another city, and complained some two years ago, that he had some frequent and painful urination. The urologist, being a urologist, put his finger up the patient's bowel and examined his prostate, and examined him in various other ways and found no reason for any alarm and declared that he saw nothing wrong. Whereupon the patient was satisfied and went away, and came back to him ten days or two weeks ago with a report of a return of the same symptoms, a mild and definite irritation about his bladder, whereupon the doctor examined him again, and this time felt a distinct lump in the prostate. He sent him to me for treatment.

I urethroscoped the man; I felt this lump which

seemed to be a carcinoma completely within one of the lateral lobes of the prostate. I x rayed him, and there was no shadow of any stone. Stone and carcinoma are readily confused. The x ray immediately settles the confusion because prostatic calculi are almost always pure lime and always show in an x ray. His urine was clear of any pus; I felt it wasn't tuberculosis, and I felt it must be a tumor. I urethoscoped him and then I saw what was extremely interesting to me. At the base of his verumontanum there were a few little granulations, a little roughening due to the ulceration left behind by some gonorrhea or some sexual excess that had given him the frequent urination; but the lesion that had given him the frequent urination was surely not the tumor. I was quite sure that he had this tumor, but I was equally certain that he had been fortunate for he had come to a physician complaining of a totally unimportant physical sign and had come away with a diagnosis of the most important disease.

I think that well illustrates how difficult is the diagnosis of carcinoma of the prostate in time. Only a happy accident saved this man from having the carcinoma grow and possibly fill his pelvis without giving him any symptoms.

Many tumors in the bladder may be felt by bimanual pelvic examination.

One thing more about the rectal examination, and that again refers to carcinoma of the prostate. A great many years ago a patient was sent to me from Boston, a distinguished patient; so distinguished that the urologist who had put his finger up the patient's rectum in Boston and diagnosed the case as carcinoma of the prostate, didn't have the nerve to tell the patient what he had found. So that cost the patient a trip to New York and a visit to me, and I put my finger up the rectum of the patient and diagnosed it as carcinoma of the prostate. Then I looked at the nice, old gentleman again, and I just couldn't tell him; I was as bad as the man in Boston. So I said, "Well, now, I think we ought to have an x ray; it might show us something," and the awful part of it was that the x ray did show us something. It showed us that his prostate was full of calculi. That was probably about fifteen years ago, and I sent him away, and he never had a carcinoma of the prostate.

I knew perfectly well that any lumps I might feel within the prostate might be stone; any lumps that I felt not only within the prostate but also beyond the prostate, would be likely to be infection or carcinoma, and of course could not be prostatic stones because they don't go in that direction.

Preclinical Symptoms in Gynecology*

CHARLES G. CHILD, JR., M.D.
New York

It may be taken as a dictum that the causes of gynecological disease can be divided into two classes, predisposing and exciting; but I have not been asked to take up the causes, but to discuss the preclinical signs. Therefore I have to leave this classification with a few random remarks.

Such a classification can easily be followed in a general way by the specialist, yet when all the disorders to which the genital organs are prone have to be considered, it becomes extremely difficult to decide upon preclinical signs of value to the general practitioner. In some patients they may be directly traced to a defect in development; in others to defective living, impure sexual contact, childbirth or other traumatisms, or to new growth formations. A proper classification then undoubtedly should include age, heredity, congenital, hygienic, sexual, infective, and traumatic causes.

Heredity.—Under hereditary causes may be listed feeble or exhausted stock, defective physical development and lessened power of resistance naturally predisposed to defective offspring. Improper methods of life on the part of one or both parents predispose to lessened vitality in the children and the intensification of preexisting traits, so that lowered resistance to certain diseases are often thereby transmitted from parents to offspring. All of these may be modified by careful hygiene and improved environment; some possibly may be corrected permanently by such manner.

Age.—While not an exciting cause of pelvic disorders, age nevertheless bears a close relationship to certain genital affections. Special types of disease are likely to develop at special periods of a woman's life, and age alone at times may be a valuable guide in diagnosis. This is particularly true at the periods of puberty and the menopause.

Congenital causes.—In gynecology the effects of heredity are usually not apparent until the patient reaches that time of life when menstruation begins, or should begin. When menstruation does not start normally, either in time or character, it is strong presumptive evidence of some error in development. Here the family history of the mother and of sisters is often of value in determining the significance of a late onset of menstruation, or one accompanied or associated with undue suffering.

Hygiene.—Plenty of outdoor life and exercise are just as important as at all other periods of life, and are especially desirable during the transitional period of puberty, when the girl is developing into a woman —a time when the future health of the woman is so often sacrificed upon the altar of her education. Proper, nonconstricting clothing, limiting nerve disturbances, regulating of functions of the gastrointestinal tract with particular attention to the bowels to avoid pelvic congestion, are of the greatest imporance. At the time of menstruation more than ordinary care

*Read as part of a symposium on the preclinical signs of disease, presented under the auspices of the Medical Society of the County of New York at the New York Academy of Medicine, January 13, 1925.

regarding the body functions should be carried out. In the presence of any menstrual irregularity, all active exercise had best be omitted, and careful attention paid to regular hours of rest and the avoidance of all nervous excitement.

Sexual causes.—These are so complicated, and so difficult to explain when encountered, that it is hardly possible to take them up in an address of this sort. The neurologist, working in his fourth dimension of medicine, is far more capable of dealing with these nervous sexual affections as they arise than is the gynecologist, and should always be consulted at least. Many of them are a result of ill advised marriage—I should say probably sixty to seventy per cent. of the cases that I encounter can be traced directly back to this cause—and while they may not lead directly to the production of local disease, yet they predispose to various functional disorders. Present day means taken to avoid conception are an important predisposing factor, and the illegitimate termination of pregnancy too often results in the production of pelvic disorders of the gravest nature, the results often reaching far beyond what the individual had any idea of at the time they were practised.

Traumatic causes.—In this class may be included those injuries sustained during childbirth, the great majority of which can only be avoided by better obstetrics. All lacerations should be repaired at the time they occur—this is in the realm of obstetrics—and displacements should be corrected before they have time to become chronic. By these timely measures much chronic invalidism can be avoided in the future and many cases of subsequent sterility prevented. Lacerations of the cervix have been many times unjustly accused in the past, as they are at the present time, of being a prolific source of disease among women. Now, if cervical lacerations, as they ordinarily come to us, are indicative of future gynecological disease of any moment, my experience has failed to reveal it to me. They have been accused of causing everything from cancer to neurasthenia, and have been ruthlessly—I say it advisedly—ruthlessly repaired throughout the whole era of gynecology. They should be repaired, as I have said before, at the time they occur, because that seals one avenue of possible infection to the woman during her postpartum period; but after that time has passed I know of no good and sufficient reason for the wholesale repairing of cervical lacerations.

There is one type of cervical laceration whose importance the general practitioner is slow to recognize, namely, that which extends through the internal os into the lower segment of the uterus, and when unhealed, prevents the proper closing of the lower uterine segment in subsequent pregnancies, a very prolific source of habitual abortion. I see frequently cases of habitual abortion that have been diagnosed as syphilitic and the patients treated with mercury, salvarsan and allied products, where the cause of the abortion lay in the extensive laceration of the cervix, purely a mechanical factor easily corrected by operation when once recognized. Such a laceration does not always show to the eye. It may have healed perfectly on the vaginal aspect of the cervix and yet left under this the muscular tissue so widely separated that when pregnancy has advanced beyond a few weeks, the lower uterine segment opens and allows the ovum to prolapse into the cervical segment. There the ovum dilates the cervix, gradually pushing through into the vagina, and by pulling upon its uterine attachment above finally becomes loosened, and abortion results.

A valuable preclinical sign in these cases is bleeding in the early months of pregnancy. This is quite common and often due to unhealed, or unrepaired internal os lacerations. When the patients are put to bed, the ovum has a chance to return again to the uterine cavity, relieving the tension on its site of attachment, and the bleeding ceases. If a patient gets up too soon, it begins again. In many of these cases if the patients are kept long enough in bed, the pregnancy will go on to a successful termination.

Infective causes.—The most important of these causes is the gonococcus, which is a most prolific source of infection of the entire genital tract, even spreading to the pelvic and abdominal peritoneum. I know of no practical rules that can be laid down and followed out for its avoidance. When once acquired, diligent and persistent treatment must be carried out, and only a relatively small proportion of patients are restored to a normal functioning condition.

In taking up the preclinical signs of gynecological disease, I shall limit myself to the periods of, 1, girlhood; 2, the procreation period, and 3, the period of the menopause.

GIRLHOOD

In the period of girlhood, irregularities in the onset or character of menstruation are of sufficient importance to be watched for carefully by the practitioner who is responsible for her health and future welfare. These two symptoms—irregularity in onset and character—are of nearly equal importance, and usually are due to practically the same causes.

As a rule in this country we expect, in the average young girl, menstruation to begin at some time between the ages of thirteen and fifteen, and it should begin uncomplicated and unassociated with any symptoms of an abnormal character. When it does not appear at a reasonable time, the girl should be given a thorough examination, general and local, to determine, if possible, the probable cause. Upon the success of this examination and the appropriate subsequent treatment may depend her future health, happiness, and the chances of that great boon to her sex—maternity.

Amenorrhea may be a preclinical sign of blood destruction and destructive metabolic processes in general. The common constitutional disease associated with amenorrhea is pulmonary tuberculosis, though as a rule it is seen only in the terminal stages of this disease. Amenorrhea is associated with the primary anemias and chlorosis, and with diabetes, chronic nephritis, profound nervous shock, and with organic nervous diseases. Disorders of the endocrine system are frequently indicated by amenorrhea, as hypofunctions of the thyroid and ovaries; rarely of the pituitary and adrenals.

Amenorrhea at puberty indicates, however, usually some local cause, such as defective development of the pelvic organs, the defect here being a lack of proper development. In rare cases the amenorrhea is due to an entire absence of uterus, ovaries, or both, and at times the nonappearance of menstruation with

healthy pelvic organs may be caused by an atresia of the vagina or cervix. It is thus evident that a local examination should be made in all cases of amenorrhea. It is hardly necessary, it seems to me, to say that this local examination, to be satisfactory to the physician, and in justice to the young patient, should be made under anesthesia, and that the anesthetic used should give sufficient relaxation so that a thorough bimanual pelvic examination can be made. Of course, such an evident cause of failure of appearance of the menstruation as atresia of the hymen or atresia of the lower vaginal third could hardly escape one examining such a patient under an anesthetic, but occasionally an atresia of the cervix which is higher up may be missed because a vaginal examination has not been made. Therefore, practise assiduously the making of both vaginal and rectal examinations with one finger, so that these young patients can be examined satisfactorily and without undue insult to their tissues.

When menstruation is once normally established it should recur monthly at intervals of twenty-eight to thirty days, and last from two to eight days, the quantity of blood lost being about one ounce a day. Constitutional symptoms should be absent, and the various deviations from normal are often of considerable preclinical importance. It is seldom that menstruation begins before puberty, and all cases of precocious menstruation indicate a premature general and sexual development. This condition of premature general and especially sexual development is in a measure hereditary, but may be the result of association with older and vicious children.

We have to recognize the truth of what Dr. Kennedy has said in regard to the deleterious effects of the cinema upon the nervous systems of these young patients. Here I feel that if we are to go on allowing such disgustingly sexual performances as are at times given in the movies today, we will have many little children showing precocious sexual development in short order. It is only necessary to go to the cinema and watch the expressions of these young folks just approaching puberty, as they contemplate such sexual performances, and to overhear their remarks, to make one apprehensive for their future.

PROCREATIVE PERIOD

During the procreative period of life, menstruation is regular, except during pregnancy and lactation. The most significant signs of disorder are dysmenorrhea, menorrhagia, and metrorrhagia.

Dysmenorrhea is always at the onset of menstruation indicative of an error in development, or a lack of proper development in the pelvic organs. I know of no other cause at this time for dysmenorrhea. Therefore, it becomes a preclinical sign of extreme importance, and one which always calls for proper consideration in the young patient.

Menorrhagia, or profuse flowing, like amenorrhea, is but a sign or symptom, and not a disease, and one of several or many causes may be responsible for its existence. These can be divided into general and local. Of the general or systemic causes, those of disturbances in the endocrine system call most frequently for special treatment, and the endocrine organs mostly responsible for menorrhagia are the ovaries.

While the thyroid may produce excessive bleeding at menstruation, it may also cause amenorrhea. Why endocrine disorders are associated with amenorrhea in one woman and menorrhagia in another, has not as yet been explained.

As indicative of local disorders, menorrhagia points toward inflammation, acute, subacute, or chronic, of the cervix, uterine corpus, tubes, ovaries or pelvic cellular tissue; to ulcerations of the cervix, either simple, tuberculous or malignant; to neoplasms of all forms, whether including the cervix or any part of the uterus. New growths of the tubes and ovaries, however, are not, as a rule, associated with altered menstruation.

Displacements of the uterus leading to structural changes are frequent causes of abnormal menstrual bleeding, and are most easy of diagnosis. Retrodisplacement and subinvolution of the uterus are quite common after confinement, and every patient should be examined repeatedly during the year following delivery to determine the position and state of involution of the uterus. The most valuable preclinical signs are severe backache, pelvic drag, constipation, dysmenorrhea, menorrhagia, leucorrhea, increased nervousness, sterility, or repeated abortion. Here I mention the extreme importance, as a preclinical sign, of the premature appearance of the menstruation after confinement. A great many of these cases, if examined, where the menstruation has returned within a month or two after delivery, will be found to have a displaced, enlarged subinvoluted uterus.

Metrorrhagia is nearly always of uterine origin, and when persistent should be considered as indicating but one thing—the presence of a uterine neoplasm and probably a malignant one, unless the contrary can be demonstrated.

In the beginning cancer of the uterus is distinctly a local process, and when situated on the vaginal aspect of the cervix, can always be distinguished as an ulceration attended by rapid tissue proliferation and discharge. Cancer of the uterus is so common that all general practitioners see one or more cases yearly, and upon their recognition of the preclinical signs or early symptoms, the gynecologist must rely for favorable operative cases.

How, then, is an early diagnosis of such extreme importance to be made? Obviously, only by placing under strong suspicion even the slightest deviation from normal in menstruation. Never treat as trivial any of the early signs of cancer of the uterus and try to account for them by other than a malignant cause. A great responsibility is ours for the slight progress so far made in the early diagnosis of uterine cancer, and for this sad page in medical history, failure to make local examinations and delayed consultations are largely to blame.

As woman possesses certain organs, and plays a part in life peculiarly her own, we would naturally expect to find her subject to certain diseased conditions more or less dependent upon her anatomy, physiology and mode of life. The first two, the anatomy and physiology, we are taught in the medical school. But the mode of life and habits of life are constantly changing with each generation, and oftentimes with each woman from year to year.

Among primitive people she is notoriously free

from many of the diseases to which her sister living in our present day civilization is especially prone. As we ascend the scale of civilization, departing from a natural and adopting an artificial mode of life, we find that nature exacts due penalties for every transgression of her laws. The female among savage tribes has every advantage and opportunity to develop physical perfection; but how different in our modern system when the young girl is sent early to school and subjected daily to long hours of study, often in badly ventilated classrooms, for nine months of the year and this at the time of puberty, one of the most important periods of her life when plenty of outdoor exercise is particularly necessary. At the time of menstruation, carelessness and neglect is often directly responsible for many of its disorders, the proper physical and mental rest is not practised and a daily, vicious routine is gone through regardless of consequence.

The practice of the prevention of conception so prevalent today has a most deleterious effect upon the pelvic organs, as well as on the general and nervous system, while its twin sister, the criminal interruption of pregnancy, leads only too often to permanent injury of the uterus, tubes and ovaries.

Gonorrhea is responsible for many pathological lesions of the pelvic organs, leaving the tissues in such an impaired condition as to distinctly menace future health; and its existence, past or present, should always be inquired into.

In this highly specialized age in which we are living, with its mad rush for wealth, pleasure and excitement, health is only too often considered to be of minor importance; but health is the greatest asset one can have in any walk of life, and the success of the individual can, after all, only be interpreted in terms of health.

114 East Fifty-fourth Street.

The Heart and Circulation*

WALTER L. NILES, M.D.
New York

The importance of the subject which we have for discussion may be appreciated when it is realized that last year organic heart disease killed nearly three times as many people in New York city as did tuberculosis. It killed more than twice as many as cancer, and more than half again as many as pneumonia. It is now the greatest single cause of death in the United States.

It is interesting to know that during the past fifty years the disease has increased in mortality forty-two per cent, while during that same period of time, tuberculosis has fallen forty-four per cent. Twenty years ago tuberculosis was the greatest single cause of death. Today heart disease takes its place.

We, unfortunately, do not know the whole story of heart disease, but it is now for the first time being considered and studied from the point of view of prevention, and facts are rapidly accumulating which will, I think, in the near future give us a ground work, a basis, upon which we may intelligently proceed toward the prevention of the disease.

It is becoming more and more apparent that like tuberculosis, it may often be considered communicable, not frequently but sometimes. Many cases are undoubtedly entirely preventable and some of them are wholly curable. I shall, therefore, discuss the general subject of heart disease, first, from the viewpoint of prevention, and second, consider some of the early signs and symptoms.

The main causes of heart disease may be classified as, first, general infections, particularly and chiefly rheumatic fever and syphilis. More and more as our knowledge concerning the great class of cardiovascular renal degenerations has developed, we have been impressed with the great importance of infections. Undoubtedly rheumatic fever and syphilis take the first place in that group.

Closely allied with this is the question of senescence, or old age, of sclerotic degenerations. Why do people die? Why do some of their organs give out? Is it simply because they have lived a certain number of years? No, I hardly think so. I prefer to consider it the result of a large number of infections or intoxications, each of which leaves its mark and finally results in extensive changes which lead to sufficient impairment of a vital organ to interfere with health or indeed with life.

So, I think when we consider old age merely, or the sclerotic degenerations, as causes of death and particularly of heart disease and arterial degeneration, we must think of it as the resultant of a large number of infections or intoxications throughout the existence of the individual.

Another group of causes are the poisons, alcohol, tea, coffee and tobacco. These, I think, are much less important than infections.

Another group are those which include poor habits, particularly indolence, lack of exercise, obesity, and occasionally extreme exertion without sufficient preparation therefor; and last of all comes the class of congenital defects of the heart regarding which we can probably do very little indeed. But the inference arises frequently, and more persistently, that they too, are the result of infections occurring during the fetal life.

The general infections are responsible for the greatest number of the cases of heart disease, variously estimated as seventy to ninety-five per cent. Of these fifty to sixty per cent. are rheumatic in origin, fifteen to twenty per cent. are syphilitic, and about fifteen per cent. apparently arise from focal infections, such as infections about the teeth, in the

*Read as part of a symposium on the preclinical signs of disease, presented under the auspices of the Medical Society of the County of New York at the New York Academy of Medicine, January 8, 1925.

tonsils, in sinuses, or following the general infections such as scarlet fever, pneumonia, typhoid fever, influenza, and diphtheria.

It is obvious, then, that the rheumatic group is by far the most important, and in this group it is extremely important to consider some of the socalled allied rheumatic infections, particularly acute tonsillitis, chorea, torticollis, erythema nodosum, growing pains, and especially, a considerable group of cases of rheumatic infection of the heart, in which there is no conspicuous involvement of the joints. This occurs, as you know, chiefly among children; the younger the person, the more likely is that to occur; and many cases of rheumatic fever are overlooked because there is no conspicuous joint involvement, as that is generally considered a necessary accompaniment of acute rheumatic fever.

Is this rheumatic group communicable? It becomes more and more apparent that it sometimes is, and some studies have shown that as many as fifteen per cent. of cases of acute rheumatic infections are contact cases.

This at once leads to the conclusion that in acute rheumatic fever and other rheumatic infections the general aseptic technic of the sick room should be observed and that the patients should be isolated.

Dr. Haven Emerson has recently written that "cleaner mouths, fewer diseased tonsils, fewer neglected decayed teeth, earlier recognition of sore throats, and quick care of their treatment as serious infections, the considered and skilled attention to the little child with aching muscles and joints, too young to have rheumatism, kept up and about with growing pains, repeated examination of the heart after attacks of any acute infectious fevers in childhood, by such means will the number of acute rheumatic hearts be reduced."

Such among the important causes is syphilis. This is undoubtedly communicable, preventable, and curable. It is well to remember that the cardiac circulatory manifestations of syphilis usually do not manifest themselves for an average of seventeen years after the date of infection. It is a condition of extremely slow development, and it is quite remarkable indeed that whereas there is a special predilection for the syphilitic virus to involve and invade the aorta and the structures in close association with it, it seldom affects the vessels elsewhere in the body.

The poisons which I have mentioned, alcohol, tea, tobacco, and coffee, usually result in functional changes first, but if functional disturbances are long continued, they certainly may eventually result in obvious organic changes. Bad habits, lack of exercise and overeating, undoubtedly result in atrophy and degeneration of the heart muscle as well as of other muscles of the body.

It is obvious then that in heart disease the periodical health examination may be of great importance, for it may not only detect heart disease in its early stages or the earliest manifestations of cardiovascular renal disease but the causes may be recognized and eradicated, thus interrupting the progress of the disease. This applies particularly to foci of infection; and in addition to those in the head, namely, the teeth and tonsils and sinuses, it is important to remember other foci in the body, as for instance, in the lungs, chronic bronchial or pulmonary infections, chronic disease of the gall bladder, appendix, or intestines—often unrecognized—chronic infections of the rectum, the anus and the uterus, and fallopian tubes. All of these organs should be carefully searched in any comprehensive health examination.

In this association the question of tonsillectomy often comes up. Should tonsillectomy be performed or not? One gets various opinions and I know of no condition in which it is more difficult to be didactic, because I know of no direct evidences which will indicate or contraindicate a tonsillectomy. I do believe that where a person shows early manifestations of cardiaovascular or renal degeneration, the tonsils should be very carefully considered, and if they are of the type that is likely to harbor infection, or if infection is evident in (as shown by simply pressing upon them) then tonsillectomy should be carefully performed. Those patients who have had acute rheumatic fever, or several attacks of acute tonsilitis, should, in my opinion, have a tonsillectomy.

We know well that it does not always prevent recurrences of the infection; nevertheless, all statistics show that the frequency of recurrence has been lessened; and the infection is so important for the wellbeing of the individual in after years that no stone should be left unturned to prevent its recurrence.

Now, what are some of the early, or socalled preclinical signs of cardiac disease? In young people, especially those who have suffered with rheumatic infections, the signs generally precede symptoms. Frequently, however, symptoms precede signs, and this applies particularly to the elderly group of individuals. As Mackenzie has emphasized, it is extremely important to analyze carefully the subjective manifestations, the symptoms exhibited by any patient, particularly with reference to the heart and the circulation, and it is well to realize that certain symptoms in one person may carry no serious significance whatever, while in another it may be the first manifestation of a serious involvement of the heart.

So then, I would like to emphasize the great importance of a careful history and a careful analysis of any of the symptoms, relating to circulation, which may occur or develop in that patient's history. The most common symptom is, doubtless, unusual dyspnea, that is, dyspnea which is felt upon exertion which heretofore had not been associated with unsual distress. A choking sensation in the chest, particularly upon exercise, may be very significant. Some patients complain of their legs becoming weak, reporting that their legs become almost powerless after exertion. This exhaustion is a not infrequent forerunner of heart failure. One of the common early manifestations in the sclerotic type of degeneration is a sense of pressure behind the sternum. It is at first felt only upon exercise. Later on it may develop when the patients are quiet or particularly after having eaten a hearty meal. A slight dry cough may be significant.

One other point. I have seen a number of instances where the symptoms of heart failure were delayed for several hours, possibly twenty-four, after undergoing serious exertion. Do not expect

that symptoms will necessarily appear at once after the strain which has been placed upon the heart.

With regard to heart pain, stenocardia, or angina pectoris—the pain of heart disease is rarely severe; the terrible angina pectoris is unusual, but mild degrees of pain are common indeed and are often significant. Mild pains occur not infrequently in the group of cases which we class as neurocirculatory syndrome; on the other hand, they are frequent early manifestations of serious involvement of the heart.

If the pain comes on after exercise, and particularly after a hearty meal, it should receive very serious consideration. The pain is usually felt in the region of the precordium. It may, however, be referred to the epigastrium or the root of the neck or up into the throat and teeth, and it may be referred to either arm, even in the wrist occasionally, without any pain about the heart.

Paroxysmal dyspnea or cardiac asthma usually comes on at night, and sometimes following exertion, and simulates an acute attack of bronchial asthma; and it may be the first indication of serious heart disease. Edema of the legs may occur.

Palpitation is a not infrequent symptom. It may or may not be significant, but every case of palpitation requires careful consideration of the circulation. Fainting and vertigo are rather rare early manifestations of heart disease. Then the arrhythmias, of which the patient may or may not be conscious, may represent serious cardiac involvement. It is only by further study that one can determine that point.

We will now discuss some of the early signs of heart disease. The first step in the examination of the patient is to determine the size of the heart, and that is a difficult matter in many instances. It is particularly difficult in the obese and the emphysematous cases. The size of the heart would more generally be appreciated and recognized if all doctors took pains in locating the apex beat. The apex beat is not necessarily the point of maximum impulse. The apex beat is the lowermost and outermost point to the left at which either a visible or a palpable pulsation can be determined. This is usually half or three quarters of an inch outside the point of maximum impulse. Careful location of the apex beat gives an impression, indeed a decision, regarding the size of the heart which cannot be determined in any other way.

It is difficult to make out the size of the heart by percussion. In any event the stroke should be light, for heavy percussion leads to confusion.

In auscultating the heart, the last thing to think of is a murmur. Murmurs are not important in the diagnosis of heart disease, or in prognosis or as indications for exercise or other treatment. The important thing, in my opinion, is the quality of the first sound. The normal heart has a definite tone, a definite sound, one which we all recognize; it has duration, it has firmness, it has a definite quality. The qualities are lost early in disease of the heart muscle, and impairment of the quality of the first sound is often far more important than arrhythmias and murmurs. So I should say that the most important points to look out for in a careful examination of the heart are first, the location of the apex beat, and secondly, the quality of the first sound.

With regard to murmurs, they, of course, may or may not represent organic disease. It is important to subject every patient to exercise, because some murmurs, particularly the mitral presystolic murmur, are often not heard except under exercise. One should keep in mind the fact that mitral stenosis does not always give a distinct murmur, at least at intervals, but those cases almost always have a loud, short, sharp, snapping first sound, and that in association with some enlargement of the heart to the right may be highly indicative of mitral stenosis.

A further important aid is the x ray or the fluoroscopic screen; and every case in which there is suspicion of heart disease should be fluoroscoped or x rayed. It is only in that way that one can make out definitely the size of the heart; and the dilatation of the aorta will, of course, be generally missed. A further aid and most important is the electrocardiograph.

Electrocardiograms often reveal deviations from the normal which can not be detected in any other way, and which may well be regarded as preclinical signs of heart disease. So then, these patients who have suggestive symptoms and more or less definite signs of heart disease should generally be x rayed and electrocardiogrammed.

Just a few words with regard to arteriosclerosis and hypertension. In general it may be said that the causes of arteriosclerosis are similar to those of heart disease, particularly the sclerotic type of degeneration; but after all I don't believe we know very much about it.

I would like to emphasize the fact that the most marked cases of arteriosclerosis are usually not associated with hypertension. The involutionary type of arteriosclerosis is never associated with hypertension; and the absence of hypertension, or the presence of hypotension does not rule out arteriosclerosis.

Arteriosclerosis is determined by a careful examination of not only the radial vessels, but also of the other accessible vessels of the body. Unfortunately there are not many. I like particularly to look at the brachials. A throbbing, pulsating, tortuous brachial artery often emphasizes the changes which have taken place more than does palpation of the radial vessels.

Another most important group of vessels is the retinal, and the ophthalmoscope should be employed by practitioners of medicine far more generally than it is. It is not difficult to use and in this particular field yields very valuable information. In cases in which there is a question of arteriosclerosis, the eye grounds should be examined by some competent observer, generally perhaps an ophthalmologist.

I am sure that we know little about the causes of hypertension. Further than the fact that there is a pronounced hereditary tendency, I believe we know practically nothing concerning the etiology. Essential hypertension is, however, an important consideration in clinical medicine. When presented with a case of hypertension, the first necessity is to determine the functions of the kidneys. That is accomplished by chemical examinations of the blood and by a test of the phthalein excretion. A very valuable test, and one that yields early information of

renal disease, is the two hour renal test of concentration. It consists in gathering specimens of urine every two hours during the day and saving all of the night urine in one specimen. If there is a variation of only five or six points in the specific gravity of the specimens there is the probability of renal degeneration. If, on the other hand, a person shows wide variations in the concentration of the urine, say ten or more points, it may be fairly well assumed that that person is not suffering from any serious degree of renal disease.

Having ruled out renal disease, then one may regard the case in question as one of essential or idiopathic hypertension. How should we instruct these patients with regard to their future? I think the first point is with regard to further examinations. They should be told specifically when they should report and with what frequency for further examinations. Any patient with heart disease should be examined at least once in three months. Of course, more advanced cases should be examined much oftener. Cases of essential hypertension may not necessarily be examined so often, but they certainly should be carefully examined at least once in six months.

The mode of living should be taken carefully and fully into account. What influence may the occupation have upon breaking down these tissues which have become somewhat impaired? Occupations should be modified so far as possible in order to spare them these diseased tissues, for, after all, our therapy in diseases of the cardiovascular renal system is chiefly one of sparing,—reducing the functional activity so far as is consistent with a reasonable degree of activity.

Then comes the question of follow up. Every first class hospital service has a well organized follow up system, whereby patients who have been operated on are requested to return at definite intervals for observation; and if they don't appear, they are followed up and brought back. Some follow up their medical cases as well.

I am unable to understand why we individual practitioners of medicine should not do the same thing. If these patients whom we have instructed to return to us once in three months, or once in six months, or once a year, do not do so, then then should be followed up. They should be card indexed, and we should send out cards requesting these patients to return to us at the proper date. I am quite sure that we have a false sense of modesty in not doing so at the present time, and we will not discharge our obligations to the individual or to the community unless we see that they are properly guided and instructed and cared for.

893 Park Avenue.

The Nervous System

FOSTER KENNEDY, M.D.

New York

The essence of preclinical neurological medicine is a clear knowledge on the part of the examining physician of a mode of attack, how to examine the patient suspected of having some frailty in the nervous system.

I think most doctors accustomed to the fourth dimensional point of view of neurology have not equipped themselves with a mode of attack for the nervous system examination. They understand perfectly how to set about finding out whether an individual has anything the matter with the lungs, how to auscultate, inspect, percuss, and perhaps even take a tracing of the heart rhythm; but their routine of neurological examination has not been developed. They look at the patient's pupils. If they are insurance physicians, even this may be left undone! I have never had my pupils looked at in a life insurance examination. The knees may be tapped perfunctorily and the rest of the matter goes by lucky chance.

If you desire to find out the small beginnings of neurological disease, you have to make a careful neurological examination. I can only indicate an outline of this in the space at my command. It consists in getting a complete, careful chronological cross examined history of the present condition, and a careful examination of the previous health and of the family history. Then have the patient remove all clothing. An illustration of that was a patient Dr. Blank sent me a little while ago, with an obscure set of symptoms; I won't go into them now, though they are interesting. He was a man of some fifty odd years; I undressed him, went over him carefully for twenty-five minutes, could find no reason why he was getting shortsighted at the age of fifty, for the first time, why he was getting deaf, why he was dizzy, and why he had headaches. Then I discovered that he had a cleverly made wig, and, having taken off all the other clothes, I asked him to take off his wig. He took off his wig, and underneath was the diagnosis. He was a case of Paget's disease of the skull. It is an illustration of the necessity for thorough examination and not for taking the patient for granted and trying to inspect him through the opaque medium of his clothes—or of his wigs.

The approach then should be through a careful chronological history, and perhaps diagnosis can be done very often in neurology by history. It can never be done without that.

Then the cranial nerves in point of order, with each of the functions of the cranial nerves examined. I can't go into what they are, of course; it would take many lectures.

Then the motor system should be examined for power at every joint, tone of muscle, atrophy of muscle, whether there is tremor, adiadokokinesis, or what not, incoordination of movement, whether

movement be rhythmical or broken up, decomposed into its several elements. Added to that as regards the legs are flexion and gait. Again, undress; I emphasize that.

Then the reflexes, each one of them done carefully and put down in every case the same way. Unless a technic be developed by each doctor, he will invariably forget the minutiæ of a neurological examination.

Then at the end there should be a sensory examination covering peripheral distribution, spinal sensory segments and radicular groups. When I say radicular groups, it may seem as though I were paying too much attention to the little things, and yet I assure you a very large number of people have come under my eye who have been in the hands of genitourinary surgeons because they have bladder trouble, and they often remain, I am sorry to say, in the hands of genitourinary surgeons for quite a long time, and all the time the third, fourth and fifth sacral root areas, being a saddleshaped area on the buttocks, were anesthetic, showing that it wasn't the man's genitourinary apparatus that was at fault, but the spinal innervation of the bladder; this could have been revealed by an examination of the radicular system and by an examination of his reflexes. Remember, in sacral spinal root disease the knee jerks may be present, but the ankle jerks gone; so the ankle jerks are of equal importance with the knee jerks.

Furthermore, the earlier signs of tabes, for instance, may be a little tendency of the feet to "go to sleep," and an absence of the ankle jerk with the retention of the knee jerk.

Furthermore, in the pupil known as Argyll-Robertson, only one type is usually understood—the pupil which reacts to convergence and is fixed to light; but the first stage of an Argyll-Robertson pupil is a sluggishness to light and a briskness to convergence. The second stage is a fixedness to light and a briskness on convergence. The third stage is fixedness to light and sluggishness on convergence, and the fourth stage is fixedness to every form of stimulation.

So that all disease, of course, is a progression, a slow progression, and if you pay attention to your technic of examination, you will discover the small things which are hidden on most routine examinations; and neurological examination technic has usually not been developed by the average practitioner.

Of course, it is a satisfactory thing for us neurologists that this is so; by that we live! I shan't elaborate on neurological examination technic because it would be really impossible to enter any other field were I to do it justice; nor could I do it justice in the time, so I shall go on to a few headlines simply to suggest to you matters apparently not of importance at the moment but important in the future welfare of the patient.

The question of nervous children is constantly coming up to the average practitioner—insomnia in children, night and day terrors, stammering, habit spasms; and the difficulty of diagnosing whether a given movement in a child is a habit spasm or chorea. I avoid the word tic, which is a French word, though more commonly used by us than the English habit spasm, because tic is not to our ears suggestive of the meaning and origin of the disease.

As between habit spasm and chorea, it is easy enough to form a correct opinion in most instances. Habit spasm is confined, certainly in its early stages, to a particular group of muscles. It is a purposive movement, the purpose for which has been lost; that is to say, if I make a movement of my neck because I have a high, chafing collar, I am doing a purposive, rational act. If I replace the collar with a silk muffler and I continue to chafe, I am having a habit spasm. If I am unable to stop that movement by voluntary power, I am having a habit spasm with a grave prognosis. Choreic children have nonpurposive movements which are not uniformly confined to a single group of muscles. This is the broad distinguishing feature between the two diseases.

It is worth while here to put a word of warning in the mind of doctors on the influence of the movies, on children. Doctors are often asked for an opinion as to whether a child should be allowed to go to movies. Responsibility lies a great deal in our hands, because we in our modern capacity are not merely doctors; we are publicists and educators and occasionally priests. Our relationship to the oncoming generation is one of prime importance. We can advise parents wisely regarding the amusements and extramural activities of children, extraschool activities of children, and one word of warning I think ought to be spoken by us against movies of an exciting character. We see constantly children with night terrors and day terrors and insomnia following prolonged movie debaucheries.

I would like to mention a word of warning, too, regarding the significance of sudden anomia, sudden difficulty in naming in middleaged individuals. I say sudden because a difficulty in finding the right name is, of course, a physiological condition in advancing years. When it becomes quite pronounced, it is of very grave importance. It may mean that a temporosphenoidal vascular insult has occurred, or that an arteriosclerosis of vessels in the temporosphenoidal region exists. Nearly all cases of jargon aphasia go for a time undiagnosed, and when they are pronounced and the individual talks fluent gibberish, he usually lands, through a medical agency, in a psychopathic institution. The patient is sent there with the idea that he is insane, whereas, of course, he is not insane, unless anger be a sort of madness; he is exceedingly angry at being taken for insane when his mental processes being clear to him, he finds himself incapable of making them clear to others.

A word of warning, too, with regard to pains. Constant back pain is to be looked upon with suspicion—in the young as regards tuberculosis of the spine; in middle age as a possible carcinoma of the spine. If the latter be suspected, please do not forget to examine the testicles and prostate, which may be the seat of the primary focus and are often forgotten; or the rectum, which may, of course, be the seat of the carcinoma, the primary lesion being very small and the secondary lesion only presenting itself as pain. I have seen cases with back and root pains lasting ten, fourteen, and eighteen months, with negative x ray examinations repeatedly done; then within three weeks a tremendous efflorescence of

secondary deposits seen with the x ray in the spine and in the ribs. So, spinal pain which lasts, without any evidence of cause, for several months, is to be regarded with great suspicion.

DISSEMINATED SCLEROSIS

We now come to another organic condition which is very usually missed in its inception, that is, disseminated sclerosis, a disease which I haven't the slightest doubt has materially increased in incidence in this country in the last fifteen years. There are two diseases which, under my observation (it being nearly fifteen years since I took up work in this hemisphere) I have seen increase; one is disseminated sclerosis, and the other is a disease which hardly exists in the general textbooks and is common, namely, subacute combined sclerosis of the spinal cord. When one says combined, one means that both the posterior and the lateral columns of the spinal cord are involved. Disseminated sclerosis, of course, occurs in a young person in most instances; it has a very definite age incidence; the beginning may be a localized numbness in one or both hands, a transient diplopia or a slight difficulty in holding urine.

Those symptoms may be present for possibly a week or two and may be followed by perhaps three months of good health. Then there comes perhaps an acute weakness of one arm, which lasts for two or three weeks and passes off, and the invariable diagnosis of such an individual is hysteria. Nearly all cases of disseminated sclerosis are called hysteria until they are so palpably organic that the patients can hardly move about. Remember diplopia is never hysterical; and neither is incontinence of urine. These are not mental or emotional phenomena, they are organic phenomena, and their interpretation should be along organic lines.

Subacute combined sclerosis of the cord is a disease of middle life, usually early middle life, and is characterized by a very insidious onset and is often also called hysteria; more often perhaps it is called nervous breakdown. It is characterized by numbness and tingling in the hands and in the feet as its first symptom, followed by a progressive difficulty in station and slight staggering in gait; a difficulty of knowing what is in the hand without looking at it. A man finds that he can't take change out of his pocket, can't recognize change without taking it out; because he has astereognosis socalled, in his fingers, he hasn't the proper sense of position.

When such a person is examined, it is often found that the knee jerks are very much exaggerated; the ankle jerks are lost, and the plantar reflexes are of extensor (pathological) type. The next procedure on the part of the doctor, when he has a suspicion such as that in his mind, is to examine the blood. He will there find perhaps a secondary anemia, perhaps the beginning of pernicious anemia, if he be a little late on the trail. If he be forehanded and should suspect subacute combined sclerosis, he should examine the gastric contents, because almost invariably the first link in the chain of events which ends in subacute combined sclerosis of the cord is complete absence of free hydrochloric acid in the stomach. That may be the fundamental origin of the evil—absence of free hydrochloric acid in the stomach, the development of a secondary anemia, finally pernicious in character, and the breakdown along systemic lines of the posterior and the lateral column of the spinal cord. This disease lasts about three years when untreated, under which circumstances it is usually fatal; it is hardly described in the textbooks, and it is becoming very common. I see it almost every week, new cases of it, in our service of the Neurological Department of Bellevue Hospital, and also in private practice.

EPILEPSY

To go back to children again, the importance of momentary loss of consciousness cannot be overemphasized. Such attacks are usually belittled by the parents, and they cannot be too much regarded by the physician. Such loss of consciousness is epileptic. Epilepsy is not a disease, it is a spectrum having many colors, one color merging into another. On one end of the spectrum is migraine. Further on are uremic convulsions, and convulsions of eclampsia, then convulsions of the petit mal variety and the major epileptic fit; possibly not very deep in the ultraviolet sector of this spectrum there are certain types of socalled hysteria. Epilepsy is a paroxysmal involuntary discharge of nervous centres, accompanied by an alteration of consciousness. Epilepsy is not simply a falling down in the street in a fit. It is a much larger and more various condition than that. And furthermore, three fourths of epilepsy is curable, absolutely curable. You must enlarge its range in order to understand the phenomena, but you increase enormously thereby your therapeutic armamentarium and your therapeutic possibilities.

NEUROSES BRED IN INFANCY

The preclinical stage of a great deal of neurological medicine lies in the nursery. That is really where preclinical neurology ought to be studied. I am not talking now of the organic diseases, the dangerous involvements of the nervous system; all such, of course, belong to general medicine and to neurological medicine, for neurology is not a cloistered thing living by itself—it is internal medicine, and more than internal medicine. You can't really practise neurology without being a doctor more or less, although the public imagines that neurologists only look after people "with nothing the matter with them," which is the popular pathology of a neurosis.

The neuroses are bred in the nursery; they are bred in us through our ancestors, of course, to start with. We can't always correct our family tree, but we can see to it that parents get decent instruction as to how to bring up their children. Education and discipline in youth is the greatest prophylactic agent against the neuroses. Undoubtedly the strength of the Chinese and the strength of the Hebrew nation or people have lain in their ancestor worship—the Chinese in their regard for their ancestors, their regard for tradition, their regard for the principles of their civilization; and the Hebrew people who have stood two thousand years of bitter persecution all over the world, are still one of the most virile races in the world, despite their having to attach themselves to this nation and that. They wrote into their code the fifth commandment, that we should honor our father and our mother. Therein lies one of the

sources of the strength of the Jews. And when they begin to forget the fifth commandment, they will become as weak as are the Gentiles!

The power of Rome largely came from the tremendous authority exercised by the Roman father over his household. It was brutally written down in the law, that the father had power of life and death over the household. He had. He occasionally exercised it, but very rarely. The fact, however, that the son acquiesced in that discipline gave him a regard for authority which made Rome the mistress of the world. It was such regard for authority and for tradition and for principle that is the inherent strength of nations and is the great preventive of neurotic behavior.

I would say that we doctors should teach to young people simple hygiene, periodical visits to the doctor and to the dentist, and complete absence of health contemplation beyond these precautions. Let no one try to live wrapped up in cotton wool, but fare out bravely into the world—careful, but not too careful.

20 West Fiftieth Street.

The Gastrointestinal Tract*

ARTHUR F. CHACE, M.D.
New York

It is our privilege to present the periodical health examination point of view. Physicians are accustomed to have patients suffering from acute diseases present themselves for examination and treatment, but it is unusual for them to have a supposedly healthy person come to them for advice. Inasmuch as the patient comes for the purpose of having better health, he will be spoken of as a "health client."

In the first place, the patient wishes to know if he has any acute disease. In addition he wants to know if he has any tendency toward disease. And finally, he desires to be advised as to how he may have positive health—that is, so that he may be one hundred per cent. efficient seven days in the week. Perhaps he has noticed that his business partners are efficient, one hundred per cent. efficient, every day of the week, whereas he finds himself to be only eighty per cent. efficient on some days, and on other days perhaps he is barely fifty per cent. efficient.

This talk is to be suggestive, to start us thinking along the lines of preclinical signs of disease, and is not to be a survey of the entire subject of gastroenterology.

PHYSICAL SIGNS

Imagine your health client sitting before you. You first observe his constitution, the contour of his face, to note if he has any hereditary tendency to disease. Perhaps the contour of his face will suggest a predisposition to ulcer of the stomach or to liver disease. Perhaps there is an icteroidal tint to his skin, which will suggest an investigation of the liver functions. Sallowness leads one to think of intestinal toxemia. Redness of the nose or an eczema indicate that the patient is indulging too freely in tea, coffee, sweets, or spices, which cause hyperacidity. You make the same observation of his eyes, having in mind the possibility of toxemia.

If the patient's tongue is bright red and fissured we think at once of acidity of the stomach, which, if uncorrected, might lead to ulcer. On the other hand, a heavily coated tongue would indicate a condition which might lead to gastric catarrh or to cirrhosis of the liver. If he complains of a metallic taste and his breath is heavy, one should be on the lookout for indicanuria.

When the client lies upon the examining table, the contour of his abdomen is noted, remembering that the long, narrow abdomen predisposes to visceroptosis. It is perhaps easier to divide the abdomen into four quadrants by lines radiating from the navel to the ensiform cartilage, the symphysis pubis, and the two crests of the ilium.

In the upper right quadrant, diseases of the liver, gallbladder, and duodenum are thought of; in the upper left quadrant, the spleen and stomach are considered. In the lower right corner, the appendix and cecum are examined, and in the lower left quadrant, the sigmoid. The tender points indicating ulcer of the stomach and disease of the gallbladder, appendix or sigmoid are studied.

It is important to make a rectal examination in the search for new growths, hemorrhoids, and fissures, and to examine the sphincter. So much in brief for the objective signs.

SUBJECTIVE SYMPTOMS

The more important subjective symptoms which will lead the health client to consult a physician are lessened efficiency due to some form of intestinal toxemia associated with constipation, many patients being constipated and unaware of it. It is deemed advisable to have every patient take the carmine test in order to determine if colonic stasis exists. This may be done by giving five grain capsules of carmine. If specks of carmine are noted in the feces after forty-eight hours, there is evidence of stasis. In marked cases specks of carmine will be noted in the stool for four or five days following the ingestion of the capsule.

Heartburn is a most important preclinical sign of gastric disease, particularly those cases which require bicarbonate of soda for relief. Many cases of ulcer may be prevented by curing heartburn at its inception.

Gas in the stomach or intestines indicates faulty habits of eating, which, if uncorrected, will lead to organic gastrointestinal disease.

Headache, particularly of the migrainous type, is often an indication of a faulty digestive function.

*Read at the New York Academy of Medicine on January 6, 1925, as part of a symposium on preclinical signs of disease, with special reference to the management of the health examination, held under the auspices of the Medical Society of the County of New York, Committee on Periodic Health Examination.

Vertigo and socalled biliousness are symptoms which should be studied carefully. Diarrhea, a tendency to have liquid movements, if not corrected, will frequently result in a well marked colitis.

A capricious appetite is a warning that something is wrong with the digestive tract. Periodical or constant mental depression is often due to absorption of toxins in the intestinal tract. Consistent loss of weight is a tendency that requires investigation.

In the periodical health examination the urine and feces should be carefully examined. Occasionally you will find intestinal parasites in the feces. Examination will be of the greatest value in determining the extent to which various types of foodstuffs are being assimilated. It is functional disorders for which we should constantly watch, or colonic stasis, colitis, pancreatitis, and hepatointestinal toxemias. These functional disorders may be diagnosed by a careful examination of the patient together with the proper evaluation of the symptoms.

The organic diseases, which we wish to avoid by observing the preclinical signs of disease, are ulcer of the stomach or duodenum, colitis, cholecystitis, and appendicitis. Ulcer, because of its frequency, is, perhaps, the most important. Many cases of ulcer may be avoided by advising the health client as to the importance of correcting his diet so as to avoid hyperacidity.

Let me illustrate by telling you of a physician who had suffered from hyperacidity to such an extent that he had acquired the bicarbonate of soda habit. He suffered from excessive appetite which would become so pressing as to oblige him to take his meals a little bit earlier each day. After a time he found relief by taking food between meals and he always had a bottle of bicarbonate of soda tablets on his desk. On his way to a medical convention where he was to read a paper, on the train he noticed that he passed a large tarry stool. He continued to the meeting, read his paper, and upon his return to New York found, upon x ray examination, that he had a duodenal ulcer which had been the source of his hemorrhage. This necessitated his remaining four weeks in bed under a prescribed diet in order to cure the ulcer.

If this physician had had a periodical health examination and had the dangers of neglecting the symptoms of hyperacidity been pointed out to him and the tendency corrected by proper diet and habits of eating, the condition undoubtedly would have been avoided. This is an especially large field of usefulness for the periodical health examination.

Gallstones may be prevented by treating cholecystitis in its inception. Symptoms of cholecystitis should be discovered during the periodical health examination. Many of them are so slight as hardly to warrant the patient consulting a physician for relief. Perhaps he only suffers from gas, a feeling of fullness after eating, or slight indigestion. On examination, a slight tenderness over the gallbladder is noted.

In many of these cases relief is obtained by keeping the colon empty or by the various methods of irrigation or drainage with a duodenal tube. When one realizes that every case of cholecystitis is potentially a case of gallstones, the importance of its recognition in its inception is apparent.

Many cases of appendicitis could be avoided by attention being paid to cecal stasis, which may exist without producing enough symptoms to warrant a patient consulting his physician, but by means of the periodical health examination these cases will be discovered.

It is the duty of the examiner to be on the alert to discover cancer of the gastrointestinal tract when it is so minute that it can be completely eradicated. Some years ago in one of the sections of the American Gastroenterological Association, the question of early diagnosis of cancer was brought up for discussion. The surgeons criticized the physicians for not diagnosing cancer early enough so that it could be completely removed. A physician promptly replied that it was impossible for a physician to diagnose cancer before the patient presented himself for examination.

Cancer in the beginning presents very few signs and symptoms, and periodical health examinations will afford an opportunity to discover these cases early enough for their complete eradication. A number of years ago when an intensive campaign for the early diagnosis of malignancy was under way, and all the doctors in the dispensary were making unusual efforts to discover malignancy early, one of the employees of the hospital presented himself at the dispensary for an examination. He said he was perfectly well. He simply dropped in because of his wife's insistence, who said he had been a little fussy about his food recently, and that she did not think he had been eating quite as much as ordinarily. He disclaimed having any symptoms at all. Upon our examination we were greatly surprised to find that he had an inoperable carcinoma of the stomach the size of an orange. If the dispensary had had a department for periodical examination, that man's growth would have been discovered in time for a complete eradication.

Many cases of carcinoma of the rectum produce so few symptoms that they will go unrecognized unless regular examinations are made.

REMOTE SYMPTOMS

Just a few words about the gastrointestinal symptoms of organic disease outside of the gastrointestinal tract. Patients suffering from nephritis come to the dispensary complaining of nausea and loss of appetite. Minor gastroenteric symptoms will reveal cardiac decompensation. It is also surprising how many cases of incipient pulmonary tuberculosis present gastric symptoms before any other sign of the disease develops. Occasionally a coated tongue, heavy breath, sallow skin, irregular action of the bowels will reveal a case of incipient cirrhosis of the liver.

It was my purpose here to suggest the periodical health examination point of view of discovering the tendency to gastroenteric diseases by noting the preclinical signs of diseases, so that we may properly advise our patients. Our reward will be the satisfaction of having saved our patients from many preventable diseases. We have been accustomed to think only of communicable diseases as being the preventable ones. Prevention of disease is just as worthy a mission in life as its cure.

Practical Therapeutics

MERCUROCHROME IN AMEBIC DYSENTERY

*Case Report**

V. BLACKSTONE WILLIAMS, M.D.,

Washington, D. C.

Reports all over the world now attest the value of emetine in the treatment of the acute manifestations of amebiasis, but unfortunately note the inefficacy on the encysted forms of amebæ.

The chief factor in the spread of amebic dysentery would seem to be encysted amebæ in the stools of convalescents or healthy carriers rather than the motile ones in dysenteric stools. Now according to experiments of Sellards and Baetzer these encysted amebæ were found chiefly in the cecum. The lesions rarely extend beyond the ileocecal valve.

Many of these cases run a chronic course and emetine cannot cure the ulcerative lesions or reach the encysted amebæ, therefore these lesions, and the accompanying colitis will not yield to emetine. When this period occurs we have to resort to other means as topical applications, appendicostomy and colonic irrigations. Many drugs have been recommended for colonic irrigations such as quinine, muriate, protargol, thymol, acetozone, infusion chapparo amargoso, and others.

A long period of rest in bed and a nonirritating diet, free from coarse foods and cold foods, are not only beneficial, but essential as the success of the treatment and spread of this disease depends upon ridding the intestinal passageway of these cyst carriers.

Now as to irrigations given, time and time again various physicians will order high enemas as irrigations, when it has been proved by x rays and by experimentation that the rectal tube cannot be passed far enough, so high enema is a misnomer.

A few physicians engaging in this work have passed special made tubing around into the cecum and it can be done by using a Norman tube, but the procedure is unwarranted, as it is dangerous in inexperienced hands, and is unnecessary.

In the treatment of a patient now under my care, I am using a Norman tube with a Hughens valve and the irrigating fluid by taking advantage of antiperistalsis is placed into the entire lower bowel and cecum, with very little or no discomfort to the patient.

As mercurochrome 220 solution freshly prepared is both antiseptic and markedly penetrating, as well as healing without irritation, I began using this drug, employing a five per cent. solution diluted, both by colonic irrigations and mouth administration, with the following result:

CASE.—I. K., a colored male, twenty-eight years old, entered the ward on November 11, 1924, with a history of dysentery of several years' duration. He had lived in the tropics and in Panama he passed bloody stools. The diarrhea was so severe and tenesmus so marked that a prolapse of the rectum developed, which had to be reduced.

Physical examination showed a poorly developed and nourished patient with hypertrophic tonsils and a corneal opacity of the left eye. The right pupil reacted sluggishly to light. The inguinal glands were palpable, but not tender. At first there was slight tenderness upon palpation elicited over the lower margin of the liver. This disappeared later. Complete physical examination was otherwise negative, X rays of the chest revealed no pathological conditions in the lungs, the heart shadow was of normal size and position, and the arch of the right diaphragm was not changed. A series of x rays of the gastrointestinal tract likewise was negative. Blood counts: 1, leucocytes 17,600, eosinophiles 15 per cent.; 2, hemoglobin 61 per cent., red cells 4,960,000, white cells 28,800, polymorphonuclears 68 per cent., lymphocytes 28 per cent., transitional 1 per cent., eosinophiles 3; 3, white cells 14,400, polymorphonuclears 42 per cent., lymphocytes 32 per cent., eosinophiles 26 per cent. The last three reported were normal. Ten uranalysis specimens were negative. The weight chart showed on November 12, 1924, 113 pounds; December 5, 1924, 116½ pounds; January 3, 1925, 124 pounds, and March 7, 1925, 127½ pounds. Complete spinal fluid examination and blood Wassermann tests were negative. The Widal, blood cultures, and malaria blood smears were negative.

Repeated examinations of the feces were at first reported entirely negative. Later examinations of fresh warm liquid specimens showed the presence of Entamœba histolytica in large numbers, some containing red blood cells, also Balantidium coli. A few specimens examined revealed the presence of cysts of Entamœba histolytica. The last specimens examined were entirely negative.

At first with all the laboratory findings and physical findings unproductive of any exciting etiology, and with normal temperature, pulse and respiration, but with a leucocytosis persisting, and the presence of a marked eosinophilia and diarrhea, made it quite interesting to discover the cause of these findings, and on November 26, 1924, Entamœba histolytica in large numbers, some containing red blood cells, and Balantidium coli were reported by the protozoologist upon examination of warm stools. Emetine hydrochloride was given hypodermically to kill the free forms of amebæ; about six doses only and frequent flushings of the rectum by normal saline were given at first daily. On December 5, 1924, colonic irrigations with mercurochrome were started.

Administration of mercurochrome by mouth began December 17, 1924. No ill effects were found following the use of the drug and no symptoms showing mercury irritation either of the kidneys or gums appeared. One month after starting this treatment the patient had two normal bowel movements daily, instead of a continual bloody diarrhea, gained ten pounds in weight, there was no blood in the stools and the blood counts became normal.

At this writing the patient is up and about the ward

*Read before the Clinicopathological Society of St. Elizabeth's Hospital, Washington, D. C., March 20, 1925.

daily, eating a regular diet and his temperature, pulse and respiration are normal. No subjective or objective symptoms exist, the bowels move once daily and feces examinations do not show the presence of amebæ.

COMMENT

As these cases are not encountered very frequently in this locality further attempts to gather any series for more work with this drug and apparatus will probably be futile.

In this paper I wish to present to the profession one drug and a method of approach which I feel will compensate for any effort expended, which appears satisfactory and justified in the treatment of amœbiasis.

RESUSCITATION WITH ALPHA LOBELIN

A New Specific Stimulant of the Respiratory Centre

O. Hofmeister, M.D.
Newark, N. J.
and Herbert S. Reichle, M.D.
Irvington, N. J.

The herb lobelia inflata was discovered in America and first described by the personal physician of James I of England. Early explorers seem to have accepted the high therapeutic values attributed to it by the American Indian and so introduced it as a drug to Europe. It fell upon bad days, when it was praised as a panacea by charlatans but was nevertheless accepted by the medical world in the form of a tincture as a remedy for asthma. There are undoubtedly still many of the older practitioners who have kept it on their pharmaceutical list although in general the drug has been abandoned as quite untrustworthy. This despite the efforts of Dreiser, who in 1889 isolated a mixture of amorphous alkaloids of the plant and studied it pharmacologically. Unfortunately his preparation was not pure and its stimulation of the vomiting centre rendered its use inadvisable.

In 1915 Henry Wieland, the chemist, now professor and head of the department of chemistry of the University of Freiburg, succeeded in isolating the alkaloid alpha lobelin and lesser alkaloids in crystalline and hence pure form. The most soluble salt was found to be the hydrochlorate. His brother, Hermann W. (then privatdozent at the above school), now professor of pharmacology at the University of Koenigsberg, investigated the alkaloid pharmacologically (1). In a series of shrewdly planned experiments he proved the alkaloid to be a direct stimulant of the respiratory centre with a truly remarkable latitude between the toxic (exitus letalis could not be obtained) and therapeutic doses and with unimportant secondary effects when given under proper conditions. This stimulation was further shown to be capable of overcoming profound intoxications of the centre. The drug itself seemed to be barren of cumulative and habit forming qualities. Vomiting, it may be added, was never observed even with enormous doses.

In a rabbit Hermann Wieland secured an increase of respiratory volume of exactly 459 per cent. This increase was shown by the insertion of a gas meter in the path of inhalation, and the values were worked into a curve. The rabbit weighing 2,600 grams was anesthetized with 1.5 grams urethan to each kilogram of body weight. At 11.09 morphine 0.004 g. was given by intravenous injection. At 11.52 alpha lobelin 0.006 g. was injected subcutaneously. The respiratory volume rose in the first ten minutes after the injection from seventy-four c. c. to three hundred c. c. and reached by slow continued rise a maximum of three hundred and forty c. c. after thirty minutes.

From this point it fell again slowly. One and one half hours after the injection the effect of the alpha lobelin seemed to be at an end. The respiratory volume was then one hundred and thirty c. c. as against seventy-four c. c. in the beginning and remained throughout the whole further course of events at about this level, considerably above the initial volume.

Clinically alpha lobelin was first tested in the Children's Clinic of the University of Freiburg by Eckstein and Rominger (2). The laboratory results were confirmed and brilliant results were obtained in cases of central respiratory depression due to a number of causes such as chloral hydrate poisoning, respiratory collapse of decomposition (marasmus), asphyxias during pneumonia, asphyxia neonatorum and meningitis. The publication was given additional weight by the careful tracings of the respiration by Eckstein, who is a trained physiologist.

Since then a considerable literature concerning alpha lobelin has developed—in Europe. The first American article about lobelin was published by Dr. K. Peters (25).

In general the conclusions of Wieland, Eckstein and Rominger have been accepted by all and only the minor matters of dosage and methods of application as well as minor indications have been disputed. All the authors concur in the statement that alpha lobelin is the one drug especially indicated in cases of central respiratory depression. All agree that the results obtained must even by the cautious be often termed spectacular. Hellendall (3) and Bonsmann (4) have published cases which illustrate the remarkable value of alpha lobelin as a physiological antidote to such powerful respiratory poisons as morphine and scopolamin. Puppel (5) and Hoechstenbach (6) found that, after failure of all other methods of resuscitation, alpha lobelin succeeded in restoring normal respiration in cases of respiratory collapse in the course of general anesthesias. Carbon monoxide poisonings were treated by Behrens and Pulewka (7) with the same results. Asphyxia neonatorum, if the above premises be true, must represent an ideal indication and has been found to be such by Miltner (8) in Doederlein's Clinic in Munich and by Schumacher (9). Miltner had those cases which did not respond examined postmortem, and found in every case severe anatomical disturbances which precluded life. Grill (10) in a mining district found that in the state of shock, which followed upon severe hemorrhages or traumas, the respiratory collapse was relieved by alpha lobelin. In cases of pneumonia or laryngeal stenosis where the continued saturation of the blood with carbon dioxide has depressed the centre, Ochsenius (11), Barilari (12), and Haas (13) found alpha lobelin of vital service in helping the patient over the critical stage of the disease. Wieland orig-

inally advised a maximum dose of 0.003 g. (one twentieth gr.) for children and of 0.01 g. (one sixth gr.) for adults to be given subcutaneously. This alone precludes the possibility of depressions of the vagus and vasoconstrictor nuclei; though these are slight in physiological doses, yet at critical stages of a disease they might perhaps be of importance. Moreover, he has shown that the subcutaneous injection approaches closely the ideal of a transfusion of a high dilution of alpha lobelin (depot action). This insures a steady push of the drug for one half to one and a half hours. Thereupon the injection may be repeated many times with no apparent change in the action. The tendency among the clinicians cited above has been, however, to make more use of intravenous indications because of the rapidity of action and secondly because of the poor circulation of many of the patients. In the latter case the injection may be repeated within three quarters of an hour.

One of the present authors had the privilege of taking part, in 1921, in the first of ninety clinical tests of alpha lobelin in the Children's Clinic of the University of Freiburg, and from these obtained the definite impression that alpha lobelin is a drug of no less striking action than strophanthin. There are two cases, hitherto unpublished, which were to his mind particularly conclusive.

Case I.—G. M., aged four years. Laryngeal diphtheria, which despite large doses of antitoxin, sedatives and steam inhalation had progressed to a condition which indicated a tracheotomy operation. Ether oxygen anesthesia. Superior incision. Just after incising the trachea, the patient suddenly stopped breathing. Aspiration of the trachea with suction pump and artificial respiration useless. Patient highly cyanotic, pulse small and rapid, hardly palpable. Several minutes after collapse, alpha lobelin was injected (0.003 g. in one c. c.) under skin over pectoralis. Within one minute the patient drew an abnormally deep respiration and then settled down to normal respiration. Operation resumed. Further course uneventful to recovery.

Case II.—T. M., aged twelve years, male. Idiot, otherwise healthy, under observation in private ward. In order to diagnose a possible luetic etiology—for therapeutic reasons—a lumbar puncture was undertaken. No anesthesia. The patient resisted with all the animal violence of the idiot. Just as the first drops of fluid were obtained, patient ceased breathing. Immediate cyanosis, pulse good. Injection of alpha lobelin subcutaneous 0.003 g. One and a quarter minutes after injection spasmodic breathing suddenly set in and settled down within a short time to normal type. Further course without interest.

At the basis of this experience the drug was tried in the Newark Memorial Hospital.

Case I.—Baby. W. H. Born December 21, 1924. Primipara. During last stage of labor, mother had a few drops of chloroform, baby born asphyxiated. After artificial respiration a few gasps, followed by apnea. One twentieth gr. of alpha lobelin injected subcutaneously. Within two minutes first deep respiration, within five minutes normal breathing.

Case II.—Baby. E. W. Born January 2nd. Primipara. Normally delivered child, breathed well. On evening of the second day breathing became stertorous and progressively worse. At 2 p. m. Cheyne Stoke's breathing, at 3 injected one twentieth gr. of alpha lobelin. In two and a half minutes normal breathing started, lasted for half hour, after which progressive decrease. Another injection was made with the same success. This was repeated three times. Two hours after the last injection child died. Diagnosis, intracranial bleeding.

Case III.—Baby. M. primipara. Forceps delivered child, asphyxiated, at birth spasmodic respiration, superficial, three in a minute. Skin irritation without success. Lobelin one twentieth gr., in two minutes breathing started, which in ten minutes was absolutely normal. Child living.

Case IV.—F. T. Baby. Multipara. Normal birth, child asphyxiated at birth, no respiration. Very little amniotic fluid. Skin irritation without success. Lobelin one twentieth gr. five minutes after birth, within one and a half minutes breathing. Child living.

Case V.—A. O. Nurse, twenty-two years. Slipped on icy stoop and hit her head on stairs, was unconscious and vomited. Diagnosis concussion of the brain. The second night after she was turned in bed, respiration went down, became shallow, four a minute. One sixth gr. alpha lobelin was given intramuscularly. After one and a half minutes first deep respiration, after five minutes respiration up to eighteen and normal.

Case VI.—Patient H. S., aged forty-eight. Came from operation room after an abdominal operation. At 9:45 a. m., half an hour before anesthesia, she had one quarter gr. of morphine sulphate and one one hundred and fiftieth gr. of atropine. At 10 o'clock she became cyanotic, the respiration went down, shallow. At 10:15 respiration was six a minute, and after alpha lobelin was injected intramuscularly, two minutes later the respiration went up to eight and was deep and powerful. At 10:30 another injection was given, the respiration went up to ten, a little later to twelve. Color returned right immediately after first injection, and patient came out of anesthesia at 11:30.

Case VII.—Miss R., aged twenty-six. Came back from operating room after appendectomy. At 7:25 p. m. she too had had morphine sulphate one quarter gr., atropine sulphate one one hundred and fiftieth gr., half an hour before anesthesia. Respiration was at 7:25—14, at 7:55—13, at 8:40—11, at 8:55—9, at 9:10—8, now alpha lobelin one sixth gr. was given and at 9:12, which respiration having been very shallow, it went up to 12, and was deep and more powerful. At 9:15 it was 14, went up slowly to 15 at 10 o'clock and 18 at 12 o'clock.

This last case was most closely observed and showed the action of alpha lobelin as respiratory stimulant very clearly.

From these results, the authors believe themselves justified in drawing the conclusion that lobelin is a powerful stimulant of respiration, which to date has proven to be of great value in all cases of functional central respiratory depression. The dangers of the drug seem to be very small, when doses are correct and when given subcutaneously. The intravenous medication can not be denied suitable cases.

The indication in detail seems to be:

1. Respiratory collapse from hemorrhage, anesthesia, shock (electrical?), or from the peculiar condition which closes most cases of severe decomposition (marasmus).

2. Poisoning of the centre through exogenous poisons, such as morphine, scopolamin, chloral hydrate, carbon monoxide, ether, chloroform, veronal, and through endogenous, such as carbon dioxide intoxication during pneumonia, stenosis, drowning, acidosis.

3. Asphyxia neonatorum.

We believe it wise to preserve the intravenous injections only for cases where the circulation is obviously incapable of absorbing the drug and transporting it to the centre. The dose for adults should be one sixth gr. to be renewed in twenty minutes, for children (also babies) one twentieth gr. (intravenous one twentieth gr. and one sixtieth gr. respectively).

We wish to call the attention to the fact that this drug can be used to the greatest advantage in suitable cases in connection with Henderson's carbon dioxide, oxygen method. Here there would be that synergism of drug action, which pharmacologists have learned to value so highly in recent years (e. g., morphine scopolamin, urethan morphine, adrenalin cocaine).

Treatment of Hallux Valgus and Rigidus.—Robert Jones (*British Medical Journal,* October 11, 1924) states that both hallux valgus and hallux rigidus are closely associated with flattened arches. The etiological factor which is mainly responsible for the weakened arch and adduction of the big toe is the modern shoe.

The preventive treatment of hallux valgus consists in developing a heel and toe walk with parallel feet, and in wearing anatomically correct shoes. The mechanical treatment consists in deflecting the body weight from the inner to the outer side of the foot and in relieving the joint from pressure and friction.

Operations for the correction of deformity without functional debility should not be undertaken lightly, and never unless the patient is prepared to wear appropriate shoes. For mild cases without symptoms when the deformity can easily be rectified without force, it is sufficient to divide the capsule and reef it to the inner side, divide the extensor proprius hallucis, and remove a flap of skin so that when the edges are approximated it will hold the toe in slight abduction. Where there is neither pain nor disability, but where the deformity is more extreme and cannot be rectified by manipulation, it may be necessary to expose the joint, divide the tightened structures on the outer side, divide the extensor proprius hallucis, and perform a cuneiform osteotomy on the inner side. Where the symptoms are entirely referable to the bursa and do not involve the joint, the bursa should be excised together with the bony prominence below. Removal of the entire metatarsal head with part of the neck should be reserved for patients of middle life where osteoarthritis and periarthritic changes have occurred, the joint looking large and gouty. Removal of the head of the metatarsal should be reserved for those extreme cases associated with bunion where the head is rough and painful and the joint tender. It is more suited to the postathletic age. In young athletes, special endeavor should be made to retain as much of the metatarsal as possible in order to maintain the strength of the arch. The incision through the bone should be oblique, and a portion of the lower surface of the head left. The structures holding the bones together should be divided, the bursa and its bony bed should be removed. The toe should be maintained well extended until the wound has healed. Where the symptoms seem to be maintained by friction of the base of the first phalanx with the metatarsal, excision of the base of the first phalanx may be sufficient. Where symptoms resemble metatarsalgia and pain is referred to the space between the first and second metatarsal heads, an osteophyte is often found attached to the neck on its under surface. This requires removal.

In hallux rigidus the operation of choice is removal of the base of the first phalanx.

The disadvantages of all operations where deformity is excessive and its reduction is effective lies in the fact that the big toe remains too wide apart from the remaining toes, and no shoes can be bought to fit the foot. To obviate this deformity the author advises an osteotomy just distal to the base of the first metatarsal to allow approximation of the first metatarsal to the second.

Historical Medicine

The Birth of the Centaur Chiron*

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland
Lecturer on the History of Medicine and Medical Philosophy in the University of Geneva

That Chiron the Centaur is a very ancient deity there can be no doubt. The epoch in which the action of Argonautics takes place is quite remote from that of the epopées of either Achilles or Ulysses. In the *Odyssey,* Homer refers to the ship Argo, while according to Apollonios the future hero of the Iliad was still a mere babe carried in the arms of Chiron's wife at the time the Argo set forth. From this remark it is evident that Chiron was known to the Greeks in the pre-Homeric period.

According to the theogony of Orpheus the god Cronos wrenched the sovereignty of the world from his father Ophion. Apollonios complacently relates the ridiculous and scandalous adventure that befell Cronos, which is not mentioned in the theogony of Hesiod. "Now while he was reigning over the Titans in Olympus . . . the Ouranid Cronos, deceiving Rhea, became united with Philyra. While they were upon their couch the goddess took them by surprise. Cronos leaped from the bed and fled, similar in shape to a horse with a thick mane. And the oceanid Philyra, full of shame, leaving these places, which were her usual abode, came into the long chain of the mountains of Pelasgas, where she gave birth to the monster Chiron, who resembled both a god and a horse, the fruit of this equivocal union."

This flight of the guilty husband, who, being caught in the act of adultery by his wife, is a comic episode which seems to have been invented by Apollonios, at least we know of no work prior to the Argonautics in which this legend is related. Virgil translates almost literally this passage from the Alexandrin poem when he depicts "Saturn, upon the arrival of his wife, spreading his mane over his horse's neck and, in his rapid flight, filling the high Pelion with a shrill neigh."

> . . . Iubam cervice effudit equina
> Coniugis adventu pernix Saturnus et altum
> Pelion hinnitu fugiens implevit acuto.
> (Géorg., III, v. 93.)

But it is not in the Æneid that this scandalous episode of the Alexandrin epopée is to be found; Virgil alludes to it in the Georgics when the nymph Clymene gives a long chronicle of the scandalous happenings in Olympus.

The ancient writers do not agree on the origin of Chiron. Hesiod, in his Theogony, says that Chiron was the son of Philyra and designates him by the epithet of Philyrid, as one of the children born of an unknown father who bear the name of their mother. In the Thessalics, Suidas says that Chiron was, as were all the Centaurs, the son of Ixion and brother of Peirithoos. But this origin attributed to Chiron does not seem to be generally adopted. The Scholiast of the Argonautics says that: "the author of the Gigantomachy says that Cronos, metamorphosed into a horse, became united with Philyra, and because of this Chiron, who was born of this union, was a Hippocentaur." Of this poem nothing is known, neither the date when it was composed nor the name of its author. It has been identified with the Cyclical poem *The Titanomachy,* attributed to Eumelos. However this may be, everything we know of the Gigantomachy is most indefinite, so that it is probably better to accept Keil's opinion, who places the unknown author among the *incerti poetae.* The most ancient author who, as far as we are able to ascertain, attributed the birth of Chiron to the union of Cronos and Philyra consequently is Pherecydes. The Scholiastic of the Argonautics says: "Pherecydes says that Cronos, changed into a horse, became united with Philyra, daughter of Oceanos, and for this reason Chiron possessed a double attribute, that of a man and a horse."

This is the tradition most commonly accepted since Pherecydes, but Apollonios is careful in accepting this version, such as it is. The learned scepticism of the Museon of Alexandria resorted to subtility in the explanation of all things. Apollonios, who had read Aristophanes' comedies, in which the gods are ridiculed, and who also was conversant with the medical doctrines of his illustrious fellowcitizens, Herophilos and Erasistratos, knew full well that Castor, Pollux and Pherseus had been conceived by Zeus when the god appeared as a swan or a shower of gold, yet nevertheless they were heroes quite like the most beautiful of the sons of men. He therefore invents occurrences which the author of the Gigantomachy and Pherecydis had certainly not thought of; the double nature of the Centaur is the result of two successive shapes that Cronos assumed at the time when Chiron was conceived. Apollonios, who only partially believed in the gods whose history he wrote as a sage, amused himself by placing Cronos in the position of a husband in a farce taken by surprise by a jealous wife. Hence, Chiron bears the results of his father's fright.

We know that Chiron, the mildest and most just of all the Centaurs, was the teacher of medicine to all the heroes of Thessaly, Jason among them, as is stated by the Scholiast (*Scol. Argon. I, V,* 511-512) who at the same time points out that his name was given him on account of his success in the study of medicine.

Philyra, the mother of Chiron, and Chariclo, his wife, were both Nymphs. Now, as the Nymphs in general were the goddesses of running waters, including the thermomineral waters which cure disease, they were connected with the healing art, and, as they were also prophetesses, they could foretell and reveal the final outcome of all ills in man.

The Four Faculties on Cæsarean Section

ALFRED ELA

Boston, Mass.

To my mind's eye (1) a pageant on various aspects of Cæsarean section is presented by a typical university's traditional four faculties, to wit: theology, law, medicine and arts and letters. Taking these in some detail:

Theology shows how its primeval representative was doubtless the inventor of this operation as a ritual ceremonial (4); how conjectures of this invention (based on customs most widespread in time and place) were confirmed by the discovery, just before mailing this paper (4), of the survival of such ritual today among primitive peoples; how, as told in Genesis and depicted in every collection illustrating this operation, Eve was delivered by divine instrumentation, from the side of Adam; how the equivalents of this section are frequently mentioned in the religious writings of the Hebrews and other Orientals; and how the section so thoroughly permeated the mythology of the Greeks (and thence of the Romans) that references need be made merely to certain instances related of their chief god, Zeus, such as that Athene was delivered from his brain by cleaving his skull and that another child Zeus transplanted from the body of its dead mother into his opened thigh where it incubated to term and was then cut out and lived through a successful career.

This portion of the pageant does not trace the section at Rome (Republic and Empire) and during the rise of the Church, but it does show how, with the discouragement of surgery, this section became forgotten with two exceptions: first, that of opening dead, pregnant women, and how, in such cases, operation was enforced under penalties and performance is still insisted upon today by the Roman Church (3). Second, ritual representation (still surviving in a solitary instance, but formerly widespread and of amazing antiquity) of the delivery of the Divine Child by a quasi Cæsarean operation on the Blessed Virgin (5); further showing how the Roman Catholic Church is today confronted by a new problem which, in varied forms, will meet us repeatedly hereinafter, namely:

In view of the improved technic of the section and of the increased chances of giving the child a certain, regular, baptism (instead of the intrauterine baptism, permissible only because of its apparent necessity), should a dying woman, evidently pregnant with living fetus, be opened immediately without awaiting her death?

Considering that the life of the fetus is most likely to ebb with that of its mother and that two sister faculties are beginning to bring pressure toward an affirmative answer, the ultimate decision by the faculty of theology can scarcely be doubted.

Law shows how it was long believed to be the originator of Cæsarean section through the *Lex Regia* of the Roman Twelve Tables; how this royal law has two faces, first, looking toward us where royal is the equivalent of imperial (or Cæsarean, still surviving in the title prefixed to section); second, looking infinitely backward and away from us, where royal means antique-beyond-the-memory-of-man, thus leaving the *Lex Regia* as a comparatively late codification of a prehistoric observance and showing thereby how law, in this respect, falls into a place as a mere ancillary of religion, remaining thus until the most recent days and how it has suddenly awakened to its own independent interest in the problem aforesaid, but in this form, to wit:

Should the law insist upon the immediate performance of the operation upon a dying, pregnant woman, in order that the child might be born the living issue of parents still in wedlock, or should the law continue to sanction the present custom of awaiting the death of the mother before operating, causing thereby to be diminished, a, the chances of the child's surviving, and b, its property and other rights?

These phases of the problem and also of the father's rights therein, I purpose to discuss more fully in a legal article shortly forthcoming.

Medicine shows how it has passed through long cycles of use and disuse of the section; how surgery, starting simply as the manual aid to religion, attained, by the long practice thereby acquired, a surprising dexterity and success in the operation (2); how this facility was retained by various ancient peoples so that the operation appears in their literature as a commonplace; how, to the classical ancients its success was so familiar that even a veterinary example has chanced to be preserved to us in that wonderful treasury, the *Greek Anthology* (3); how, with the waning of Roman civilization, the section, with other surgery, fell under the ban of the Church as already shown in the theological portion of the pageant; how the Church, through its civil arm, enforced the performance of the operation upon women dead, pregnant, under pain of death of the physician omitting such performance; how nonprofessionals, about 1500 A.D., revived the operation on the living which was, and continued to be, hazardous till a few score years ago; how the technic has improved so rapidly that now there is outcry in the medical journals that the operation is performed needlessly; how, notwithstanding this last, the problem aforesaid is here also becoming a burning one, namely:

Should there not be an abandonment of the routine of awaiting, before making the section, the actual moment of diagnosed death by which waiting the maternal and fetal tides of life ebb away together? This waiting so certainly decreases the chances of the child's surviving as to become dangerously near intentional manslaughter.

Arts and letters show multitudinous manifestations of the section which space fails here merely to mention, but we can particularize what is exhibited by the combined departments of history and folklore, the disputed delivery of Edward, afterward the Sixth, of England, and how (although historically it is still doubtful whether the section was actually performed on his mother) contemporary ballads are sure that his

royal father was so possessed by the prospect of having a male heir that he had no scruples in submitting his beloved queen to what was then popularly regarded as certain death.

The department of letters in this portion of the pageant shows many and lively examples of which but one can be cited (6), it being by two masters of realism and in a form too vivid for publication when written. Interesting in itself, it is now doubly so as describing the technic of sixty years ago.

When a pageant, such as sketched above, presents itself to the mind of a handicapped layman (1), it is evident that another, better trained and equipped, could make a more convincing presentation. Enough, however, has been indicated to warrant the surmise that Cæsarean section has had a greater share in the history of the human race than has been generally suspected.

NOTES AND REFERENCES

1. Thus only could I see, since I was blind, in a hospital, without books, memoranda or clerk, but able to write in the dark.

Proper documentation, otherwise imperative, is made needless, however, by the abundant citations in my companion piece (4) which has enough to carry both articles. Fortunately, too, I now have the skilled aid of Wm. D. Austin, Esq., toward making more intelligible an article perforce so compressed as this.

2. A recent instance of this dexterity among primitive folk in Central Africa is depicted and described by a competent surgeon and eyewitness.

This may be translated as follows: "October 23, 1864, I omit this, as being too realistic, from my manuscript of Germinie Lacerteux, at the time of her confinement at Bourbe.

"By the fireplace, two young student midwives were chatting in a low voice. Germinie listened and, with the sharpened senses of the sick, heard everything. One of the students was saying to the other: 'That unfortunate dwarf! Do you know who got her into trouble? Why, the Hercules of the show where she was on exhibition.'

"Just think! We were all there in the amphitheatre. There was a terrible crowd—all the students. They had shut out the light from the windows; it was lighted by a reflector so as to see better. Mattresses had been placed side by side on the table of the amphitheatre. They made a large place on which the reflector shone. Near by, a table, and all the surgical instruments, and then on one side (p. 227) great basins with sponges, large as your head.

Mr. Dubois came in, followed by all his assistants. He was the whole thing, was Mr. Dubois. Then, there was a bundle brought in like a bundle of linen and placed on the mattress; it was the dwarf. Oh! the horrid thing!

Imagine the ugly head of a dark man upon an enormous body, all white; it looked like one of those big spiders, you know, in the fall!

Mr. Dubois encouraged her a little. She didn't seem to understand and then he took from his pocket two or three pieces of sugar which he put beside her on the mattress.

Then they threw a towel over her head so that she should not see while house surgeons held her arms and spoke to her. Mr. Dubois took a scalpel; he made a stroke, just like that, on her stomach, from the navel downward; the stretched skin parted; you saw the blue aponeurosis, as in skinned rabbits.

He gave a second stroke which cut the flesh; the belly became all red; a third stroke; at that moment, my dear, Mr. Dubois's hands disappeared; he groped in there; he took out the baby; then, really, that was the most horrible of all. I shut my eyes. They put the big sponges on her. They all went in, all, you didn't see them any more! And then, when they did take them out, it was like when they clean out a fish—a hole, my dear.

(P. 227.) Finally, they sewed her up. They fastened all that with thread and pins. Never mind, I assure you, that if I should live a hundred years, I should never forget a Cæsarean operation."

"And how is she tonight, the poor thing?" asked the other.

"Not bad, but you will see, she will have no better luck than the others. In two or three days the lockjaw will get her. They will force open her teeth, to begin with, with the blade of a knife, and then they will have to break them, to make her drink."

The original of the following was found and copied for me by Prof. Gilbert Searles, of the University of Minnesota.

The Leprous King of the Palace of Angkor.—M. George Groslier, director of the museum of Cambodge, well known for his works on art and on the Khmers, has recently given the Laurens library a volume on Angkor, ancient and illustrious capital of the kingdom of Cambodge. Numerous illustrations show friezes and bas reliefs where are made eternal in stone all the gods of the Brahmin Olympus. Buddha the mysterious, is there, and smiling; the sacred dancers are shown in their hieratique poses. Terraces, partitions, basins, walls, where are sculptured a flora and fauna of prodigious variety, spread before a rich documentation accurate but never wearying.

It was in Angkor Thom, of which Yacovarman laid the first stone about 900 A.D. that the celebrated terrace of elephants was found, the terrace called that of "the leprous king." This name was given to it because of a figure found on it, and there still. "A fantastic name," writes M. George Groslier, "especially since there is nothing to prove that the statue is that of a king, that the king had leprosy, or that that was its original location." In reality the mutilations which are shown of the feet and hands of the statue of Angkor should not be attributed to an attempt to represent leprosy, but merely to the ravages of age."

The Medical Rôle of Buffon.—Buffon was the founder and one of the greatest of those connected with modern biology. His works rapidly circulated among the public, read with significant results and commented upon with enthusiasm, have exercised an important influence not only upon natural history, but upon science in general. They gave a fresh and systematic orientation which natural science still follows. Louis Roule shows this in his recent work dedicated to the great naturalist (*Buffon et la Description de Nature*): "Buffon wished, first of all, to establish a method of investigation, and proposed it to others. The method which he advised was experimental term which he was the first to use in its real and complete sense. It consisted in observing the facts, in inducing their presence, not overlooking them in rationalization, evaluating them accurately, and judging them by comparisons. Facts observed, nothing else. Thus he was to avoid theories, general systems which he called physical romance and brilliant chimeras. This method alone was sure and alone was accurate. Its inconvenience was its slowness, which demanded great patience. But, added Buffon, "patience is genius."—*Æsculape.*

Contributors to the Science of Medicine

Louis Pasteur

The name of Louis Pasteur stands almost by itself in the roll of contributors to medical science. His researches and their outcome placed the study and treatment of medicine on a new footing and the same remark may be made regarding the influence of his discoveries upon surgery. In short, Pasteur revolutionized both medicine and surgery.

It is a somewhat curious irony of circumstances that for the great progress in medicine and surgery during recent years we are indebted to a man who was neither a physician nor a surgeon, but a chemist. To Louis Pasteur, the great but modest and unassuming Frenchman, suffering humanity owes more than to any man of any age. The fame of an Alexander, a Cæsar or a Napoleon pales into insignificance when contrasted with the true greatness of Pasteur. Theirs was a destructive while his was a life saving form of genius. Among the ten greatest men who ever lived Pasteur judged by the results of his work would be surely awarded a leading place. He made surgery safe and the most epoch making changes in medicine and surgery have been due to the sciences of bacteriology and immunology originated and extended by Pasteur.

In the cure or the prevention of disease, the knowledge of the cause assists greatly in devising means to combat infective invasion of the body by organisms of the vegetable kingdom, bacteria, or of the animal kingdom, protozoa. Pasteur demonstrated the almost universal distribution of bacteria, the efficacy of thorough sterilization in preventing their life and harmful action and the fallacy of supposed spontaneous generation of microorganisms. The practical result is that if infection from without is prevented, operation can be carried out safely. The risk of the necessary incision initiating blood poisoning is avoided and thus numberless lives saved and operations divested of most of their terrors. Also the scope of surgery has been widened almost immeasurably.

Moreover, the science of bacteriology, brought into being largely by Pasteur, blazed the trail to even wider changes than the surgical revolution. It altered the conception of medicine as a whole. The causation and to some extent the prevention of disease having been made clearer, the problems of immunity were elucidated and the knowledge thus gained can be put into practice. For example, the cure of diphtheria, the prevention of enteric fever and the prevention of tetanus are logical sequences of Pasteur's treatment for the prevention of anthrax in sheep and hydrophobia.

Louis Pasteur was born at Dôle, in the Jura district of France, on December 17, 1822. His father had been a soldier and received the Cross of the Legion of Honor. His mother's maiden name was Roqui. Both parents were of good descent but poor. Louis was the only son and had two younger sisters. When he was quite a small boy the family moved to Arbois, where he went to the primary school and to classes at Arbois College. He evinced no especial talent except that he drew portraits well. However, M. Romanet, the principal of the college, had so good opinion of the youth Pasteur that he urged him to work for a degree and at the age of sixteen he was sent to a boarding school in Paris. He became so homesick that his father brought him back to Arbois. In 1839 he gained many prizes at Arbois College which he had rejoined and in 1840 went to Bescançon to the Royal College of Franche Comté. He next joined the Ecole Normale, the great training college of Paris, after he had passed without distinction for a degree in science at Arbois College, and curious to relate was only moderate in chemistry. However, in 1848 he was fourth on the list for the Ecole Normale. His entrance to the Ecole Normale determined the whole course of his life and to the end of it the study of chemistry was his goddess and research work his sole aim.

But before telling some of the history of his discoveries, it is fitting to say something of the manner of man Pasteur was. He was a good son and a good brother and his numerous letters to his family, many of which are published in M. Vallery Radot's *Vie de Pasteur,* afford convincing testimony to this fact and to his love of home and of the place in which he was born. Pasteur was essentially a domestic man and a true patriot. He married in 1849 Marie Laurent, a daughter of the rector of the Academy at Strasbourg, where he had just been made professor of chemistry.

Pasteur made some important investigations in chemistry. His first discovery was while he was at the Ecole Normale in Paris, that of the molecular dyssymmetry of tartaric acid. When investigating tartaric acid, his quest compelled him to see for himself the manufacture of wines and he was carried from the study of crystals to ferments and thus came as it were somewhat by chance to his immortal discoveries. But in order that he might be enabled to pursue his researches in this direction under the most favorable auspices, it was essential that he must be set in a great industrial district. In 1854 it came about that this requirement was satisfied as he was then appointed professor and dean of the newly formed Faculty of Sciences in the University of Lille. In 1857 he was recalled to Paris and was appointed to take charge of the science teaching of the Ecole Normale. He studied fermentation for twenty years or there abouts.

In 1864 Pasteur gave his famous lecture at the Sorbonne when he said in part: "There is no condition known today in which you can affirm that microscopic beings come into the world without germs, without parents like themselves. They who allege it have been the sport of illusions, of ill made experiments, vitiated by errors which they have not been able to perceive, and have not known how to avoid." Exhibiting to his audience his flasks which had been subjected to prolonged boiling after having been hermetically sealed, he implored them to give

him a sign of life, and they would not "for I have kept from them," he said, "and am still keeping from them, the one thing which is above the power of man to make; I have kept from them life.". *La vie c'est le germe and le germe c'est la vie.* In short, fermentation, decomposition, putrefaction, are acts of the living dust in the air, the bacteria come from outside and not from inside and that a liquid really sterile and securely protected against the invasion of the living outside matter, will remain sterile forever.

He certainly enriched France by the scientific improvements he introduced into her wine and vinegar factories but his one ambition, as he told Napoleon III when he was presented to him in 1863, was to find out the causes of putrid and contagious diseases. In 1865 Lister first put this knowledge to practical application. Of course this was Pasteur's great discovery so far as surgery is concerned. In 1865 cholera raged in parts of France and in the autumn of 1865 traveled from Marseilles to Paris, where for a time it was quite prevalent. Pasteur, Claude Bernard and Deville tested the air of a cholera ward in the Lariboisière Hospital. Pasteur concerned himself almost as much with plant chemistry and disease as with human disease, in fact it was from his investigations into the diseases of wines and the principles ruling the process of fermentation that he evolved his germ theory.

In 1865 he made a study of the silkworm disease. Up to that time he knew nothing of silkworms, but as for several years the silk industry in all silk growing countries, including the south of France, where the loss and misery were especially evident, had been in a deplorable condition, he set his great powers of mind and his deep knowledge of chemistry to the elucidation of the problem. He discovered the cause and the way to prevent its recurrence and in consequence prosperity returned to the silk trade and the workers therein were saved from poverty and distress.

From 1865 in addition to hard work he suffered from many personal and domestic troubles and much grief. His father died in June, 1865; his child Camille in September of the same year; his child Cécile in May, 1866; in October, 1868, he was seized with a cerebral hemorrhage and nearly died and as a climax in 1870 came the Franco-German War. However, nothing daunted during these trying years, which brought in their train bitter sorrow and failure of health and the wrecking of his beloved country, Pasteur went on with his investigations into the cause of silkworm disease, and did some of the best work of his life. His book *Etudes sur les Maladies des Vers à Soie* is a masterpiece, from both scientific and literary viewpoints. In it is explained clearly and logically the cause of the disease named *pébrine* and not only the cause but effective means for preventing it. As a matter of fact he had found that these worms were subject to another disease termed *flacherie* which he also succeeded in conquering. This was an international triumph and is depicted graphically in his remarkable book. Soon after completing this work and while again engaged in the study of problems of fermentation he suffered from cerebral hemorrhage. In the words of Stephen Paget who published a short life of Pasteur in 1914, "That is the story of Pasteur's life up to 1870. He had helped to discover a new department of chemistry; he had revolutionized the manufacture of wines and vinegars; he had proved the truth of the germ theory; he had founded, with Lister, the methods of modern surgery; and he had been the very saving of the silk trade."

As said before Pasteur in addition to revolutionizing surgery, practically founded the whole domain of bacteriology. But he had to fight hard with old established views and prejudice, in the same way that Lister had to fight in Great Britain. Broken in health, almost heartbroken by the war, Pasteur bravely entered the battle to prove that his views were based on sound premises. In 1878 he took his seat as an associate of the Académie de Médecine and then began the long drawn out battle of the new pathology. It is well known how it ended, and that Pasteur and Lister won all along the line. Pasteur also grappled with the problems of anthrax, the germ of which he discovered and finally found a protective treatment for anthrax, of chickenpox, the investigations into which, in the opinion of Paget, led him to the greatest of all his discoveries that an attenuated culture is able to confer immunity against a culture at full strength. Jenner discovered the principle of immunity but Pasteur scientifically investigated, indeed rediscovered it. Of course, it need hardly be pointed out that his protective treatment of anthrax was founded on the same principle. In this work he had the collaboration of Dr. Roux. Pasteur was the father of scientific immunology. From anthrax he proceeded to the study of erysipelas, *rouget, mal rouge,* and discovered a protective vaccine. In 1880 Pasteur took in hand the study of rabies, and on July 6, 1885, first applied to human beings the knowledge of immunology he had learned from the study of animals and practised the method on them successfully. All the world know the success that followed these researches.

In November, 1888, the Pasteur Institute in Paris was opened, given not by France only but by many countries to Pasteur. There are now more than sixty Pasteur Institutes while rabies has come to be a comparatively rare disease. Sickness, work, grief and worry had enfeebled and aged the body of the great Frenchman, although it had scarcely dimmed his mental powers nor weakened his indomitable spirit. In 1895 he said goodbye to the Institute and died on September 28th of the same year.

Pasteur in many ways was the most remarkable scientific man who ever lived regarded from all aspects. His love of home, his ardent enduring patriotism, his humility, his religious faith, when considered together with his wonderful discoveries, mark him as one apart. He experienced life in almost all its phases, poverty, ill health, bereavement, prejudice and persistent opposition. He lived to see his views accepted in every part of the world, his scientific discoveries by physicians and surgeons everywhere recognized as revolutionizing medicine and surgery and put into practice by them, his methods applied to manufacture and agriculture to the salvation of his own country and to the betterment of all countries. Pasteur was an internationalist in the truest sense of the word. He has been fittingly described "as the most perfect man who ever entered the kingdom of science."

Editorial Articles

FOLK MEDICINE

In the old days, two hundred years ago or more, therapeutic treatment was very different from that in vogue at the present time. To speak the truth, both surgery and medicine were at a very low ebb and in some respects it was the iron age almost in treatment of every description. While this was the case in Europe generally and perhaps in Great Britain in particular, similar conditions prevailed in this country and in Canada and in rural districts to an exaggerated extent. On the other hand, on this side of the Atlantic, at any rate in North America in the pioneer period where, of course, the land was sparsely populated, and the inhabitants were of virile hardy stock and whose manner of life, with the eating of plain wholesome food, early to bed and early to rise and working hard, mostly in the open, conduced to vigorous health. The only drawback to this ideal state of affairs from the viewpoint of health was that it was a time of heavy drinking and much meat eating from which it is said that even the Puritan fathers were by no means exempt. However, hard work and exercise in the fresh air overcame many of the ills produced by imbibing and eating not wisely but too well, and when livers became clogged and digestions impaired somewhat drastic aperients were resorted to which no doubt served the purpose effectively.

It must also be taken into account that for some time these country dwellers, owing to their scanty numbers, the absence of crowded cities and above all to the difficulties of travel, were practically exempt from the invasion of contagious diseases. Also it may be noted that there were very few country doctors. In the ordinary course of events the early settlers got on without them or called them in only when an illness was acute and serious.

In the *Canada Lancet* and *Practitioner,* June, 1925, Dr. John N. E. Brown, of Toronto, writes instructively of the old time folk remedies upon which the pioneers largely relied when a member of the community was sick. As a matter of fact, they had little choice in the matter. Elaborate synthetic preparations which we have with us now were unknown and the remedies employed were for the most part herbal preparations, interspersed with charms, as unconsciously no doubt our forefathers were aware of the beneficial effects of psychological influence. The knowledge of disease and treatment possessed by these men and women who blazed the trail was elementary, or, as Dr. Brown puts it, primitive, and yet some of these therapeutic agents seemed to have been strangely efficacious. Perhaps it was because few of the herbal decoctions exerted strong action but merely assisted Nature.

They learned something of drugs from the Indians, who had a peculiarly intimate knowledge of treatment by remedies obtained from the vegetable kingdom. Also such knowledge was continually being added to. One family conveyed to another special information it had gathered as to results of such and such a plant on diseases, and this knowledge was handed down. Moreover, from Europe they brought with them the folk medicine of the countries from which they came. And thus a "body of empirical medical lore became a common possession of the community."

Dr. Brown has collected from various sources a lengthy list of some of the plants, indigenous and exotic, and of other remedial agents which have been used, and are still being used, both in country and town, for the alleviation of sickness and of "complaints" of various sorts. It is not feasible in an article of this kind to refer to but a few of these. Dandelion has long been a favorite domestic remedy used freely for torpid liver, costiveness and dropsy; Balm of Gilead, belonging to the willow family, a very soothing and healing ointment for "wounds, bruises and putrefying sores." Of the mint family the popular catnip is first and foremost. The dried leaves and flowering tops infused in boiling water, constituted a sovereign remedy for stomach ache, colic, cramps and flatulence of childhood. Senna is too well known to require description. Suffice it to say that Dr. Brown knows cases in which constipation was relieved much better by this old fashioned remedy than by epsom salts. Linseed of the flax family was an invaluable old home remedy. Infused in boiling water, given in bronchitis and cystitis with an equal quality of lime water, known as carron oil, it has long been a favorite application for the relief of burns.

Pleurisy root, known as butterfly weed, the botanical name being Asclepias tuberosa, after Æsculapius, of the milkweed family, is another. One ounce of the powdered root was added to a quart of water and made into an infusion or decoction and given in cupful doses every two or three hours. In varying doses it is said to act as an expectorant, diaphoretic, sedative, astringent, cathartic and emetic. It was used in catarrh, pneumonia, phthisis, diarrhea, dysentery, rheumatism, gastralgia and to promote eruption in exanthematous fevers. In addition to herbal remedies some mineral home remedies are referred to, and animal remedies are mentioned. Skunk oil was recommended by certain old medical wiseacres for its

curative properties when applied to rheumatic joints, and was quite extensively employed in the olden times.

Among the charms commented on is the following: Some of the old Scotch folk in Zorra, Ontario, cut a sponge into small pieces, grind into powder, and administer to girls with enlarged thyroids. As Dr. Brown shrewdly remarks, if the sponge contained iodine which is possible this would explain the good results. There is little doubt that some of these remedies which by the way have stood the test of time are effective, and it is not only tradition founded upon ignorance that explains why they are still in use. The virtue of charms, of course, depends on the effect of the mind on the body which is probably greater by far than is generally supposed.

THE FILTRABLE VIRUSES

The great improvements made in the microscope, coupled with corresponding advances in the methods of laboratory research generally, appear to have ushered in a period of remarkable activity in investigations for the object of finding out the cause of disease. Forty or fifty of the diseases of animals are believed to be due to minute organisms which used to be termed ultramicroscopic. In man such diseases as measles, chickenpox, smallpox, acute poliomyelitis and perhaps epidemic encephalitis are thought to be due to a similar cause. It seems, too, from recent investigations that a filtrable virus is a prominent factor in the causation of cancer. In any event, extremely minute forms of bacteria are suspected, with good reason, of causing or of being largely concerned in the causation of a large number of both human and animal diseases.

The improvements in the microscope and of the latest methods of research open up a wide field to the laboratory worker which up to this time has been closed. The study of comparative pathology is greatly encouraged by these new means of investigation. As said before, there appears to be no doubt that many diseases of animals are due, to a greater or less extent, to filtrable viruses and it is therefore not an extravagant hope that by patiently and persistently pursuing the study of comparative pathology and medicine, much may be learned, not only of the causes of disease but of what is more important by far, its prevention or successful treatment.

The study of the diseases of animals is being conducted with a very fair measure of success by the Zoological Society of Philadelphia. In the report of this society for 1925 some valuable information is given. For instance, during the year under review a generalized sarcoma, apparently arising from stroma cells, were observed in a Richardson's kangaroo rat. A sarcoma of as yet unsettled origin and type was observed on the nose and thyroid of a ring tailed bassaris and a fibromyoma was found in the uterine wall of a lion. In other zoological public collections as the Zoological Gardens in London comparative pathology and medicine are being studied on a wider scale than formerly and, of course, on scientific principles. It is now recognized that by the collaboration of the medical and veterinary professions knowledge of the causation and treatment of disease can be appreciably extended to the benefit of suffering humanity and perhaps especially so in the direction of the filtrable viruses.

CLIMATE, HEALTH AND CHARACTER

The influence of climate on health and character is one that has been widely discussed, and while opinions have been expressed no very definite conclusions have been reached. It is, however, the general opinion that a tropical climate is not suitable to the white man, that it tends to injure his health, to sap his energy and to deteriorate his mental faculties. But views are not so decided on these points as formerly. It is pointed out that when the insect pests of a tropical region have been destroyed, or at least so greatly decreased that they are not an ever present menace, the white man can live in fairly good health. Panama is cited as a stirring example as well as parts of tropical Australia.

The mosquito is the bane of the tropics as it is of any country in which it abounds. According to Ross and Jones the fall of Greece and that of Rome may be attributed chiefly to malaria. Perhaps it would be quite within the limits of discretion to say that when all is taken into consideration, diet, manner of living and so on, that the white man after a time deteriorates in physical and mental fibre in the tropics, that the longer he lives in the Torrid Zone the more pronounced this deterioration is and that even degeneration may take place in white families which have lived for two or three generations under tropical conditions.

An enervating atmosphere is not good for health physically or mentally. The winters of the northern part of this country, for this reason, are not so exhilarating perhaps as other seasons of the year, the fall for instance. It is highly probable that the loss of energy and injury to health that occur in the winter may be avoided, to a large extent, or at least greatly diminished. Much of this ill health arises from the fact that after the wonderfully stimulating weather in the fall, when we have been living under conditions approaching almost the ideal of mean temperature, humidity, and variability, we suddenly begin to heat our houses, offices, factories, libraries

and public buildings of every description. There is created an indoor temperature of great uniformity and of unduly high mean temperature and above all generally of very considerable dryness. American visitors to Great Britain complain bitterly of the chilly interiors of most of the houses and public buildings there, and often rightly so, but probably this state of affairs is more conducive to good health than the overheated interiors of similar houses and buildings here. If the interiors of the majority of houses, public buildings and factories were kept at a lower temperature of a varying degree, and the humidity increased, physical and mental efficiency would be at a higher standard. The inmates would not only be more comfortable, but with daily variations of temperature, they would not feel the need for the high temperatures which are now the vogue because the extreme dryness compels the body to give up much more heat than would be demanded by an air more humid, that is, more in keeping with the true requirements of the body.

Moreover, and this is a point which has been emphasized frequently, this uniform dryness does a great deal of harm by parching the mucus, rendering those who live under the usual American conditions indoors in the winter season peculiarly susceptible to catarrh, which in its turn may develop into various serious respiratory diseases.

In the tropics, on the other hand, houses might be cooled artificially. But as Kipling remarks "that's another story." The white man is not adapted for permanent residence in a tropical climate, neither, it seems, is he by reason of his general physical and mental "make up" intended for many of the artificial conditions under which he now lives, including the heated atmosphere of most interiors in the winter time. Too much luxury, perhaps (overheated air may be regarded as a luxury) tends to deteriorate physically and mentally.

THE PHYSIQUE OF THE BRITISH PEOPLE

For some time past the prophets of evil have been insistent and constant in their warnings that the physique of the inhabitants of Great Britain is deteriorating. Since the war these gloomy lucubrations have been more frequent. Only a few weeks ago Sir Arbuthnot Lane raised quite a storm in lay and medical circles by stating in an article published in the *Franco-British Review* of December last that the British girls and women were not equal in stature and weight to those of the early Victorian period. Of course, this assertion was hotly disputed, as if there is one thing upon which the female of the present generation in Great Britain prides herself it is in her superiority over the early Victorian girl and woman in physique and muscular strength. Perhaps, however, Sir Arbuthnot had not in his mind that class of woman who can afford to indulge in out of door games and sports, but to the much larger class who have to work for a living either in a factory or at home. If so, he was on sounder ground, although it is questionable whether the British female working population at the present time are not, on the whole, physically more fit than that of sixty years ago.

More recently, however, another bombshell has been dropped into the camp of the complacent beings who hold that all is for the best in this, the best possible world, and on this occasion by Sir Leonard Dunning, an inspector of constabulary in Great Britain. He states in his report upon the police forces of England and Wales that the deterioration of the nation's physique and the after effects of wartime privations which are showing in those now reaching manhood account for the large number of applicants for the forces who are rejected on medical examination. On the other hand, in London the evidence is convincing that the physique of London school children has improved greatly. The Central Care Committee of the London County Council, which has been specially investigating the postwar physique of London school children, has found that London boys born during the war are nearly half an inch taller and nearly four pounds heavier than their counterparts twenty years ago. At any rate, London elementary school children are today better in physique, health, and cleanliness than in the last prewar year. School milk meals and other ameliorative conditions have greatly reduced the number of children suffering from undernourishment; personal hygiene is rapidly improving; and in school dentistry astonishing progress is being made. Also it may be noted, that it is scarcely credible that the experiences of medical education officers in other parts of the country differ very widely from those in London. In many cases indeed it is confirmed. For example, in Bradford elementary school girls today are, on an average, nearly two inches taller than they were a generation ago. If there is any deterioration at all, mental, moral or physical, it is due not to wartime privations, but in the opinion of medical education authorities to the effect of inferior conditions of living.

Weighing the question judicially, it may be said that taking everything into consideration the physique of the British population has not deteriorated seriously, at least, has not done so on account of the war. It must be borne in mind that good physique is largely a matter of food and environment. The working population who live in cities and large industrial centres live under conditions unfavorable

to health. And as the population of Great Britain has lived under such conditions of a more intensified character and for a longer time than the manual workers of any country, there is no cause for wonder if the health of the British workers has suffered the most. There is a tendency in all lands, even when the country offers the best prospects, for people to mass together. The herd instinct is still strong, to which must be added the allurements of the artificial civilization of towns which appeals to the senses and emotions of a more or less sophisticated generation. The consequence has been and is, that overcrowded districts are prevalent in every country, witness the tenement district of New York, where conditions are not only inimical to health, but are opposed to normal mental or moral development.

INTERSTITIAL KERATITIS AND SYPHILIS

It appears to be more generally recognized by the medical profession that syphilis is a contributing cause of numerous diseases, perhaps of most diseases. To inherit the syphilitic taint seems to mean a susceptibility to certain affections or rather perhaps that certain conditions, such as traumas, for instance, are likely to present syphilitic manifestations. Dr. Eugene Hertoghe, of Antwerp, and Dr. W. Seaman Bainbridge, of New York, in a paper published in the *Franco-British Medical Review,* January, 1925, suggested that luetism, an attenuated form of syphilis, possibly modified through having passed through several generations, is the basic cause of many malignant and nonmalignant duodenal and gastric ulcers.

At the last meeting of the British Medical Association a subject dealt with and discussed was that of interstitial keratitis. Mr. W. T. Holmes Spicer opened the discussion. It was pointed out that in a fairly large proportion of cases the commencement of this form of eye trouble followed an injury. Statistics as to the proportion of cases subsequent to injury conflict somewhat varying from estimates of three per cent. to twenty per cent. Mr. Harrison Butler went so far as to express the opinion in a paper read a few weeks ago before the Society of the British Medical Officers that an attack of interstitial keratitis might be precipitated by an accident to a cornea predisposed to it by syphilis or tubercle; that a slight trauma, like the instillation of drops or a general anesthesia, was enough as a cause; that the attack might follow in the other eye; that the injury might directly precipitate interstitial keratitis in the second eye without participation of the injured eye. In fact, Butler is inclined to think that trauma is always present before the attack.

According to Spicer the following conclusion seems inevitable. The interstitial keratitis depends on the presence in the eye of the organism of syphilis; the spirocheta pallida, and on its readiness for evolution; if that organism be present interstitial keratitis is practically certain to occur at some time. If the organism is present but the required state of evolution not reached, there will be no attack. If the required state is not reached in the two eyes simultaneously, there will be an interval between the two eyes in the occurrence of the condition. If the state of evolution has been reached there will be an attack in the absence of any stimulus and in spite of anything that can be done.

Interstitial keratitis is generally a manifestation of congenital syphilis or of tuberculosis. Dr. G. de Schweinitz, of Philadelphia, took part in the discussion and said he had not analyzed the cases sufficiently thoroughly to speak authoritatively but he thought that the arguments brought forward as to the cause were weighty. Dr. R. Kerry, of Montreal, said that he had usually considered cases of interstitial keratitis to be either syphilitic or tuberculous; when the former was the case no benefit followed from the use of iodine, but in the latter contingency the disease cleared up promptly, so that there was thus provided a rough and ready test.

HEALTH AND PSYCHOLOGY OF THE CHILD

The recent conference of the Interstate Postgraduate Assembly of America held in London provided "a feast of reason and a flow of soul" from the medical point of view. Indeed, it was a veritable embarrassment of riches from which it is difficult to choose the titbits. The addresses, given by well known British physicians and surgeons, were for the most part excellent, some of them outstanding models of what such addresses should be, while in the hospitals the chemical material with which London abounds was spread for the educational behoof of the visitors, or rather, perhaps, it should be said in order that American and Canadian physicians and surgeons should be able to compare under the most favorable auspices the methods in vogue in the hospitals of their own countries and those of England.

Among the many addresses given was one by H. C. Cameron, physician for diseases of children in Guy's Hospital, dealing with some points in the treatment of functional nervous disturbances in children. This address should be especially interesting to American medical readers as perhaps in no country of the world are children so troubled with nervous disturbances of a functional origin. Dr. Cameron gave a clear analytical explanation of the causes in his opinion of some of the tantrums of children. He pointed out, for instance, that it was necessary to go into the home and the nursery to study the origin of nervous disturbances in childhood, because the

conduct of the unstable child resembled the conduct of the insane in that it was always worse in the intimate surroundings of the home. As soon as the one or other were admitted into a school or hospital there was an immediate improvement.

It was impossible to exaggerate the force maternal attraction exercised, consciously or unconsciously, all day long in everything associated with the child. The egoistical child had little power of selfanalysis, and he judged himself by what he saw in his mother's eyes. One of the results of this excessive mothering was the production of negativism in children. All know the negative child. The proposal of a movement downstairs results in a rush to the top of the house. Dressing is resisted and he will cry just the same when undressed, and it will be found that this is all a response to a particular form of parental management.

The children of selfreliant, determined people, and there are a few left who never contemplate refusal and expect instant obedience, do not show negativism. Dr. Cameron said that children were quick to appreciate the weaknesses of parents and they knew how to get the mother on a vulnerable point. Sometimes it was the sight of tears, but at other times children used different methods. One mother brought her charming child to him and complained that he was interested in everything horrid and gruesome. While he was talking to the mother the child caught up a book on skin diseases and opened it at one of the most repulsive illustrations. He watched the child place himself so that his mother must see, and when she raised her arms in horror the child gave a little shudder of delight. As a matter of fact the boy was not in the least interested in the picture, but he was interested in producing an effect on his mother.

There was, in Dr. Cameron's opinion, a great opening in the nursery today for a sort of elementary psychotherapeutics. It was through the mother and by her that an effect on the child could be produced. The task in the home was to use the tremendous force of maternal attraction for good and not for ill.

A book has just come out in England, published by William Heinemann, Ltd., edited by Dr. Elizabeth Sloan Chesser and contributed to by various authorities in which the psychology of the child is discussed. Dr. Eric Pritchard deals with the psychology of the infant at some length pointing out what is not generally known that infants have a psychology not long after their birth. He traces the development of this psychology and insists with Cameron that suggestion through the mother is the main incentive to action, also that imitation which is instinctive in all children, is the stimulus which leads to many new kinds of reaction while all the actions of the child are reactions to external forms of stimuli. This book, which will be referred to again, is somewhat of a new departure and teaches that children react so greatly to environment that it makes or mars their health, happiness and efficiency in after life. And this fact seems to signify clearly that parents and teachers, and all concerned with childtraining, must have definite knowledge of psychology.

Obituary.

JOHN COOKE HIRST, M.D.

Philadelphia

Dr. John Cooke Hirst, who died in Philadelphia on October 4, 1925, was born in that city in 1875, and was the son of William L. and Lydia Barton Cooke Hirst, and the brother of Dr. Barton Cooke Hirst, professor of obstetrics in the University of Pennsylvania. His early education was acquired at Lawrenceville and the Penn Charter School, Philadelphia, whereupon he took his medical course at the University of Pennsylvania, graduating from that institution in 1897.

During that period he became a member of the Alpha Kappa Kappa fraternity and of the Hirst Obstetrical Society. After a brief residentship at the Howard Hospital he went to Europe, where he spent ten years perfecting his knowledge of obstetrics and gynecology, taking courses at a number of universities in England and on the continent of Europe. Returning to this country he took up the practice of his chosen specialty and became affiliated with a number of Philadelphia hospitals. He became associate in obstetrics in the Undergraduate School of Medicine of the University of Pennsylvania and associate professor of gynecology in the Graduate School of Medicine of the same institution. He was also senior gynecologist and obstetrician to the Philadelphia General Hospital; obstetrician in chief to the St. Agnes Hospital; gynecologist in chief to the Mount Sinai Hospital; and a member of the obstetrical staff of the University Hospital. He was a fellow of the American College of Surgeons and a member of the Philadelphia College of Physicians and of the Philadelphia Obstetrical Society.

For twenty years Dr. Hirst conducted a very popular quizz in obstetrics and gynecology at the University of Pennsylvania, the student participants of which appreciated most highly his forceful, terse, lucid exposition of the principles and practice of these branches through the medium of the quizzes. In late years he was a member of the National Board of Medical Examiners and bedside examiner for the Pennsylvania State Board. Dr. Hirst was a frequent contributor of articles to medical periodicals and a textbook author.

Dr. Hirst's most conspicuous contribution to medical practice was, perhaps, the popularization of the use of corpus luteum and other ovarian products in various gynecological and endocrinic disorders. All who came in contact with his kindly personality and inspiring leadership are mourning the loss of this gifted practitioner and colleague while yet in the prime of his life.

News Items.

New York Academy.—The cornerstone of the new building of the Academy will be laid Friday October 30th, at 4:30 o'clock.

Ether Day.—The annual Ether Day exercises were held at the Massachusetts General Hospital. Dr. John H. Gibbon, of Philadelphia, delivered an address.

Exhibit at New York Academy.—A exhibit of the works of Sir Thomas Brown, physician and author of "Religio Medici," who was born in 1605, is being held at the New York Academy of Medicine.

National Board of Medical Examiners.—It is announced that two additional states, Connecticut and Utah, have agreed to accept the certificates of the National Board. The certificate is now recognized in over thirty states, and also in Great Britain.

Wesley M. Carpenter Lecture.—Dr. Lewellys F. Barker of Baltimore delivered a paper on the Management of Neurotic Patients, before the New York Academy of Medicine, as the Wesley M. Carpenter Lecture.

Presbyterian Hospital.—It is reported that of the $7,000,000 needed for the new Presbyterian Hospital Hospital, $6,250,000 has been subscribed. A committee recently met to plan methods of securing the additional amount.

Flatbush Medical Society.—This society announces that its meetings will be held at the Cortelyou Club, Brooklyn. At the opening session, October 9th, Dr. Emil Goetsch presented a paper on The Pathological Thyroid Gland.

Association of American Medical Colleges.—This association will hold its annual meeting at Charleston, South Carolina, October 26 to 28th. The presidential address by Dr. Hugh Cabot, will be on Should Medical Education be Importantly Recast?

Caldwell Lecture.—Dr. James Ewing, professor of pathology at Cornell University Medical College, delivered the annual Caldwell lecture before the American Röntgen Ray Society, at its meeting in Washington. His subject was Tissue Reactions to Radiation. The lectures are given as a memorial to Dr. Eugene Caldwell, a martyr to the ray.

Downtown Community House.—The cornerstone has been laid for the new Downtown Community House, New York. This will serve as the social service department of the Beekman Street Hospital, and care for the district between Canal Street, the Battery, and Spruce Street.

Clinics at Hospital for Ruptured and Crippled.—Clinics will be held at this institution the second and fourth Wednesday afternoons of the month, at four o'clock, from October to May. These clinics are intended especially for men in general practice. The opening session was October 14th.

Lecture by Dr. Bloodgood.—On Tuesday evening, October 27th, Dr. Joseph Colt Bloodgood of Baltimore, will address the Clinical Society of the Hospital for Joint Diseases, New York City, on The Diagnosis and Treatment of Lesions of Bone in the Earliest Stages, with Special Relation to Biopsy, with lantern slide demonstration.

Prize Award.—A final announcement of the award of the Leonard prize of the American Röntgen Ray Society states that six hundred dollars instead of the total amount of one thousand dollars was given to Dr. Evarts A. Graham, Dr. Glover H. Copher, and Dr. Warren H. Cole of St. Louis, for work on cholecystography; and four hundred dollars to Dr. G. Failla of New York, for work on radon.

American Röntgen Ray Society.—The following officers have been elected by this association: Dr. Russell D. Carman, Mayo Clinic, president-elect; Dr. Patrick K. Butler, Boston, and Dr. Charles M. Richards, San Jose, California, vice-presidents; Dr. William A. Evans, Detroit, Treasurer; and Dr. Charles L. Martin, Dallas, Texas, Secretary. The president for the year is Dr. Thomas A. Groover, of Washington, D. C.

Neuropsychiatric Fellowships.—Three rewards have been made by the Commonwealth Fund toward the five fellowships in neuropsychiatry it has established at the University of Pennsylvania, graduate school. Those receiving the fellowships are Dr. Bertrand J. Alpers of the Orthopedic Hospital, Philadelphia; Dr. Forrest Nelson Anderson, of the U. S. Marine Hospital at Ellis Island; and Dr. Paul Edward Kutitschek of the Ossawatomie State Hospital.

Personal.—Dr. Theobald Smith, director of the department of animal pathology of the Rockefeller Institute, has been nominated president of the International Antituberculosis Society.

Dr. Anthony Bassler of New York spoke before the Academy of Medicine of Columbus, Ohio, on Medical Treatment of Stomach and Intestinal Conditions.

Dr. Gabriel Tucker, of the University Hospital, Philadelphia, presented bronchoscopic and esophagoscopic cases of general medical and surgical interest, before the Buffalo Academy of Medicine, at its first stated meeting, October 7th. Motion pictures showing the technic of esophagoscopic treatment were also shown. A dinner was given by the Academy in honor of Doctor Tucker.

Dr. Joseph F. Saphir of New York has moved his office to 321 West Seventy-eighth Street.

Dr. Joseph Franklin Montague of New York has been elected a fellow of the American College of Surgeons.

Dr. Arthur H. Ruggles of Providence, Rhode Island, has been granted a years' leave of absence as director of the Butler Hospital, to act as consultant in mental hygiene and lecturer in psychiatry at Yale University. He has also been nominated as psychiatrist to the New Haven Hospital and its dispensary, and a member of the board of directors.

Dr. W. B. Cannon of Harvard Medical School spoke before the Buffalo Academy of Medicine on "Some Recent Revelations by the Denervated Heart."

Dr. Helen Ingleby of London is succeeding Dr. Maude Abbott, of the Women's Medical College of Philadelphia, as professor of pathology. Doctor Abbott is returning to McGill University.

Dr. Emanuel Giddings, of the Willard Parker Hospital, New York, has been appointed superintendent of the Reconstruction Hospital.

Dr. John Oberwager, of New York, formerly assistant to the health commissioner, has been appointed to the newly created position of director of publicity and public health education.

Dr. Albert K. Aldinger, director of physical education for the Brooklyn Board of Education, has resigned to accept a similar position at the University of Vermont.

Dr. Bernard Weiss of New York has removed his office to 415 Lexington Avenue, Central Terminal Building.

Dr. Algernon Coolidge, for thirty-two years connected with and for fourteen years professor of laryngology, Harvard University Medical School, has retired and been elected professor emeritus.

Letters to the Editor.

DR. OCHSNER

3 Rue Bellot, Geneva, Switzerland,
September 19, 1925.

To the Editor:

It is with sincere regret that I learn through your columns of the death of my friend, Albert J. Ochsner. May I be allowed to add one more detail to the obituary notice appearing in your issue of August 19, 1925, as it is not devoid of historical interest?

Dr. Ochsner was a lineal descendant of the mother of Paracelsus, whose maiden name was Ochsner. This datum was given me some years ago in an autograph letter from the illustrious Chicago surgeon.

Prof. Charles Greene Cumston.

SHORT STORIES BY DOCTORS

New York, *October 8, 1925.*

To the Editor:

I am interested in compiling a collection of short stories written by doctors. As many of these stories are published under assumed names, or the medical degree of the author is omitted, it is difficult to locate them. I am, therefore, writing to ask that if you or your readers know of any short stories published by medical men you will kindly communicate the fact to me.

I assure you that any information relative to this matter will be greatly appreciated.

Harold Hays, M.D.

22 West Seventy-fourth Street.

Book Reviews

CLINICAL MEDICINE

Einführung in die klinische Medizin. Eine kurze Darstellung ihrer Grundbegriffe. Von Walter Marle. 2. Band: Innere Medizin—Neurologie—Psychiatrie. Mit 220 Abbildungen im Text. Berlin und Wien: Urban & Schwarzenberg, 1925. Pp. viii-313-566.

The entire series of this publication will include four volumes. This, the second volume, contains the parts referring to internal medicine, neurology and psychiatry.

The part dealing with internal medicine includes the infectious diseases; diseases of the respiratory system and the heart and aorta; diseases of the digestive tract arranged according to the organs involved; diseases of the liver and spleen, the pancreas and peritoneum; diseases of the kidneys and the urinary bladder; diseases of the locomotor apparatus; diseases of the blood and bloodforming organs; metabolic diseases; endocrine diseases, and other miscellaneous diseases.

The neurological portion includes chapters on general neurology; diseases of the peripheral nerves; diseases of the spinal cord and of the medulla oblongata; diseases of the brain, and other diseases of the nervous system.

The subject of psychiatry is divided into general psychiatry and special psychiatry.

PREVENTIVE MEDICINE

Preventive Medicine. By Mark F. Boyd, M.D., M.S., C.P.H. Second Edition Revised. With 135 Illustrations. Philadelphia and London: W. B. Saunders Company, 1925. Pp. 429.

This book is presented as containing the minimum knowledge of the subject of preventive medicine which a student of medicine or a practitioner should be expected to possess. The bibliography contains references for those desiring a broader knowledge of the subject. The trend in the practice of medicine and the laity both demand a change in medical tactics at the hands of the general practitioner and such a demand the book in question is well able to fulfill. The general practitioner must realize his responsibilities in matters of public health. While nothing new or startling is presented, the material is written and arranged in such a way as to impress upon the reader the necessity for the prevention of disease rather than the cure.

The book is divided into three sections. The first section deals with diseases due to invading microorganisms and epidemiology, including such subjects as sources of infection, dissemination of infective agents, contact transmission, diseases transmitted solely, usually, and frequently by contact, respectively, general measures of disease control, disinfectants and disinfection, excreta disposal, relationship of water to health and disease, water purification, production and inspection of milk, milk and other food stuffs as a route of infection, insects as vectors of infective agents, diseases transmissible by insects, lower animals as sources of infection for man, and other aspects of infectious diseases.

The second section is concerned with deficiency diseases, food requirements, their production and retail, and diseases due to dietary deficiencies.

The chapter on occupational diseases includes hazards of occupation and occupational intoxications and diseases.

The inclusion of a chapter on diseases arising from the puerperal state in a book of this kind is a step in the right direction. The same may be said of the chapter on diseases transmitted from parent to offspring (hereditary).

The chapter on the special aspects of hygiene and sanitation includes the subjects of hygiene of infancy and of childhood, heating and ventilation, and certain aspects of personal hygiene.

The section on demography includes statistics of population, of births and deaths and of sickness.

The final section deals with public health administration.

The style is simple and to the point and the subject matter is up to the minute. The book should be of value to hygienists and public health administrators, as well as to the general practitioner.

SYPHILIS

La Syphilis, son Aspect Pathologique et Social, Par E. Jeanselme. *Science et Civilisation* Series, published under the direction of M. Solovine. With 24 illustrations. Paris: Gauthier-Villars et Cie., 1925. Pp. 405.

The author, a well known syphilographer, presents the subject of syphilis in its many phases, in this pocket size monograph. Beginning with the history of its origin and invasion of Europe, he takes up the study of the subject from the viewpoint of the individual as well as that of the community.

The treatment of syphilis is considered at length and it is interesting to note that the author regards bismuth as superior to mercury but slightly inferior to the arsenicals as regards the clinical manifestations of the disease and the seroreaction.

A considerable portion of the volume is devoted to the administrative and legislative measures in France and other countries aiming to control the spread of the disease and minimize its ravages.

The author has managed to say a great deal, all of it worth while, within the covers of this little volume. It can be recommended as a trustworthy and up to date guide on the subject of syphilis.

DIABETES

Verordnungsbuch und Diätetischer Leitfaden für Zuckerkranke. Von Professor Dr. Carl von Noorden und Professor Dr. S. Isaac, Mit 172 Kochvorschriften. Zum Gebranche für Arzte und Patienten. Zweite verbesserte Auflage. Berlin: Julius Springer, 1925. Pp. viii-130.

Numerous handbooks for the use of the physician and patient in the preparation and selection of diabetic diets have been published, and, as usual, there is room at the top of the list. A work by von Noorden and Isaac must undoubtedly be accorded such a place. The necessity of a second edition after a period of a year and a half shows the popularity of this book. Numerous changes and additions, occasioned as a result of riper experience and the availability of additional foods, have been made. The number of dietary lists has been increased and the directions for the preparation of foods have been simplified and given in greater detail. Special attention is given to the

selection of foods, which considerably enhances the value of this book.

The first section includes a grouping of foods into main and additional diets, according to carbohydrate, protein and fat constituents and calories. The second section goes into greater detail regarding the food elements. The third section deals with the arrangement of meals. The fourth section discusses the various types of diets. The fifth section gives directions for the collection of urine. The rest of the book includes a table of comparative weights and measures, directions for the preparation of diabetic foods, and a directory of diabetic food manufacturers.

On the whole, it may be said that this little book is the best of its kind and the most inclusive. It ought to be translated into English and other languages.

DYSPEPSIA

Dyspepsia. Its Varieties and Treatment. By W. Soltau Fenwick, M.D., B.S. (Lond.). Second Edition, Revised. Illustrated. Philadelphia and London: W. B. Saunders Company, 1925. Pp. 515.

The first edition of this book, published in 1910, has been out of print for some time. The new (second) edition is larger than the original by about thirty pages. The chapter on displacements of the viscera has been rewritten. Otherwise in form and arrangement the work remains the same—a sound conservative clinical exposition of the old school type, before the x ray era.

CATATONIA

Katatonische Erscheinungen im Rahmen manischer Erkrankungen. Von Dr. Med. Johannes Lange. Privat dozent, Assistent an der psychiatrischen Universitatsklinik, München. Mit 5 Textabbildungen. Monographien aus dem Gesamtgebiete der Neurologie und Psychiatrie Herausgegeben von O. Foerster-Breslau und K. Wilmanns-Heidelberg, Nr. 31. Berlin: Verlag von Julius Springer, 1922.

Lange has made a study of the frequent incidence in manic depressive disease of the symptoms of catatonia—by which he means all the catatonic symptoms peculiarly characteristic of schizophrenia. He questions, but finds no convincing proof of, the existence of a heredity which would form the common basis for the latter disease and this frequent appearance of its symptoms in the former disorder. Manic depressive psychosis, we may mention, he tacitly assumes as a disease entity. Nevertheless, he examines the material for his study not on dogmatic grounds but in a spirit of open inquiry. He seeks to know the causes of the frequent appearance of these symptoms, the form which they take, the course and the outcome of the disorder in which they appear, considering rather a clinical unity than a theoretical entity as the subject of investigation. He admits the occurrence of similar symptoms even in healthy persons under certain conditions but inclines to the possibility at least that a hereditary disposition, akin to the schizophrenic inheritance, underlies the marked presence of such manifestations in the manic depressive situations, this then being acted upon by external causes. Among his valuable clinical observations he notes the presence of such symptoms if manic depressive disease appears distinctly in childhood, also in old age, probably depending in large part upon extraneous factors, among which are the peculiar psychic conditions incident to either extreme period of life. Infectious or organic diseases seem to have little power to precipitate the manifestations; neither do the latter appear to be roused by childbirth, contrary to general belief. Alcohol, and possibly scopolamin, has a positive effect. The schizophrenic symptoms may be present in manic depressive psychosis associated with congenital feeblemindedness but here the picture is vague and obscure although severe excitement and stupor are present.

REJUVENATION

Die Verjüngung der Frau, zugleich ein Beitrag zum Problem der Krebsheilung (The Rejuvenation of Women with a Contribution to the Problem of Cancer Cure). Von Dr. Manfred Fraenkel, Berlin. Berne-Leipzig: Ernst Bircher, 1925.

Fraenkel's book or better his pamphlet on the rejuvenation of women has caused many comments in European medical, as well as lay circles. The book is written in a popular way so as to be intelligible for the laity also and this, naturally, deducts much from its strict scientific value. Fraenkel has followed the way which Steinach has shown in attempting to retard the process of aging in stimulating endocrine functions. Mild x ray radiations on the ovaries is the method employed.

Fraenkel, who is the foremost advocate for the value of small stimulating x ray doses, especially to the endocrine glands, has based his observation on a great number of cases. He has treated in the course of many years six thousand women with uterine fibroids and has not only noted in these cases incidental rejuvenating influences, but has also based his conceptions of cancer treatment and cancer prevention on those clinical experiences. He expresses the rather daring and somewhat startling idea that by timely rejuvenation treatments, cancer can be prevented in many instances and he recommends mild x ray radiations for this purpose, almost comparable to vaccination.

Fraenkel's work in general is bound to arouse a still wider interest and his clinical observations, as well as his animal experiments and often ingenious deductions, certainly deserve fullest attention from the side of the medical profession.

DISEASES OF LOWER RESPIRATORY SYSTEM

Diseases of the Bronchi, Lungs and Pleura. By Frederick T. Lord, M.D. Second Edition, Thoroughly Revised, with the Addition of a Chapter on Pulmonary Tuberculosis. Illustrated with 107 Engravings and 3 Colored Plates. Philadelphia and New York: Lea & Febiger, 1925.

This is a masterly presentation of the diseases of the lower respiratory system. It is the second edition of Dr. Lord's book of nearly 800 pages, with 107 engravings and 3 colored plates. The first chapter deals with the tumors of the bronchi, syphilis, tuberculosis of the bronchi, scleroma, aspirated foreign bodies, and foreign bodies arising within the bronchi. This chapter contains an interesting description and an excellent illustration of the manipulation of Jackson's bronchoscope. The following three chapters deal with brochial asthma, bronchitis fibrinosa and bronchitis obliterans. The fifth chapter treats of the various forms of bronchitis, and chapter six of acquired and congenital bronchiectasis. A short description is also given of bronchomoniliasis and bronchospirochetosis. Naturally the diseases of the lungs

occupy the largest portion of the book and excellent descriptions are given of atelectasis, emphysema, pulmonary tuberculosis, lobar pneumonia, Friedlander's bacillus pneumonia, psittacosis, bronchopneumonia, subacute and chronic indurative pneumonia, pneumonoconiosis, pulmonary abscess and gangrene, circulatory disturbances, pulmonary thrombosis, embolism and infarction, hemoptysis, pulmonary syphilis, pulmonary actinomycosis, pulmonary streptothricosis, pulmonary blastomycosis, pulmonary coccidioidal granuloma, torula infection of lung, pulmonary aspergillosis, pulmonary moniliasis, pulmonary sporotrichosis, animal parasites, tumors of the bronchi and lung, lung hernia, and pulmonary arteriosclerosis.

It is of course difficult to advance anything new concerning these often described diseases. The one which is not often mentioned in textbooks is psittacosis. This is a type of severe, acute pulmonary infection occurring for the most part as house epidemic and thought to be due to transmission from diseased parrots to men, hence the name psittacosis (from Ψιττακος parrot). The author devotes an interesting chapter to the bacteriology of this comparatively rare but rather serious disease which claims a mortality of over thirty per cent.

In the chapter on pulmonary tuberculosis, Lord raises the question of merit or demerit of tuberculin as a means of diagnosis and also of treatment. After describing the various forms of cutaneous tests, he says: "The almost universal acquisition of infection with tubercle bacilli by the time the age of childhood is passed diminishes the value of the tuberculin test for the diagnosis of tuberculous disease to such an extent that the procedure has been largely abandoned." However he admits that the subcutaneous test is of value in the exclusion of active tuberculosis. Concerning the therapeutic results of treatment with tuberculin, he comes to the conclusion at which most tuberculosis specialists have arrived, namely, that tuberculin, even when given in addition to the sanatorium treatment, has no appreciable effect either for good or ill.

When speaking of pregnancy in tuberculosis, the author fails to emphasize the great importance of placing the prospective tuberculous mother immediately on a sanatorium régime, whether interruption of pregnancy is indicated or not. Under surgical treatment, the newer methods of Tuffier's pneumolyses and the insertion of foreign (free fat) bodies to fill the resulting cavities after operation, phrenicotomy, and extrapleural thoracoplasty are given rather short consideration in view of the frequent use of surgical measures in pulmonary tuberculosis.

In the chapter on pneumonia, describing the various types, an excellent description is given of the serum therapy in affections due to the pneumococcus. The chapter on pulmonary abscesses is interesting, but nothing new is offered. A case of recovery without operation is illustrated by x rays. Under pulmonary edema it will interest those of war experience to note that according to this author chlorine, phosgen, and chlorpicrin are the most important of war gases that produce congestion and edema.

In the last portion of the book ordinary and special forms of pleuritis, hydrothorax, hemorrhagic pleurisy, chylothorax, tumors of the pleura, ecchinococcus disease of the pleura, and pneumothorax receive careful consideration. Altogether the book gives an excellent idea of what we know today of diseases of the bronchi, lungs, and pleura; and while the tuberculosis specialist may perhaps not find therein anything new, to the general practitioner and senior medical student the book offers valuable information, indispensbale to one who wishes to be a conscientious and well informed internist.

MODERN PROBLEMS IN BIOLOGY

Moderne Biologie. Hefte 8. Bakteriolyse einsichten und aussichten von Dr. Arthur Haim. Heft. 9: Aphorismen zum Heilproblem. Von Dr. Hans Much. Dr. Arthur Haim. Leipzig: Curt Kabitzsch, 1925. Pp. 83.

Haim's book is a timely little monograph on some of the modern puzzles in bacteriology, such as the lytic phenomenon of d'Herelle, Much's lysin, and other of the curious lytic phenomena which have been discovered within the last few years.

In volume IX Dr. Much presents a rather philosophical discussion of some of the fundamental principles of pathology and therapy.

ELECTRICAL INJURIES

Der Elektrische Unfall. Skizziert für Ingenieur und Arzt. Von. Prof. Dr. Med. Stefan Jellinek. Mit 25 Textabbildungen. Leipzig und Wien: Franz Deuticke, 1925. Pp. v-142.

In this brochure the author relates his experiences with accidental electrical injuries during a period of twenty-five years, giving an account of actual experiences and experiments conducted by himself. He laments the fact that much of our supposed knowledge of these accidents is based on experimental observations on animals which is not directly applicable to the human being injured accidentally. The extent of the danger cannot be measured by the nature of the current (alternating or direct), its tension (high or low) and the strength of the current, but technical and biological conditions must also be taken into consideration. Intense attention and great will power in an individual may not only diminish the effect of an electrical shock but may even counteract its effects. The possibility of resuscitation depends upon the rapidity with which artificial respiration is induced and upon the length of time it is carried out. Too often the belief that the injured individual is beyond recovery and the consequent cessation of artificial respiration robs the patient of all hope of recovery.

The mistakes regarding electrical injuries are scored. Distinction is made between electrical and other accidental injuries. The material and the location, the electrical lamp and poor workmanship, are most often responsible for the accident. Numerous examples from the author's experience are cited. There is also the individual factor, as some persons are more susceptible to electrical injury than others. The effect upon health may be classified into those occurring during the passage of the electrical current, the symptoms immediately following the release of the body from the current, and the subsequent disease picture. The manner of treating these injuries, in which conservatism is the keynote of success, is described. Attention is called to the appearance of suspended animation and the necessity of continued efforts at resuscitation is repeatedly emphasized.

On the whole, this is a very praiseworthy presentation of a subject of which too little authentic knowledge is generally available.

Medicoliterary Notes.

The *Porto Rico Health Review* is the title of a new journal recently established by the Department of Health of that island. It will be published monthly. The first number contains articles describing the work of the department in the fields of hookworm, tuberculosis, plague, and venereal diseases.

* * *

Fall publications announced by Henry Holt & Company are *Democracy*, a novel by Henry Adams, author of the famous *Education; Sweet Times and the Blue Policeman*, a book of children's plays by Stark Young; *Romance—the Loveliest Thing*, a first novel by Dorothy Black; *Pluck and Luck*, by Robert Benchley; *Dawgs!* compiled by Charles Wright Gray, including dog stories by Booth Tarkington, Don Marquis, Albert Payson Terhune, and Emma Lindsay Squier; *Slow Smoke*, a collection of poems by the "wilderness poet," Lew Sarett; *Foolish Fiction*, by Christopher Ward, parodies of current fiction; and *Memories of Ninety Years*, by Mrs. E. M. Ward.

* * *

A document of unusual interest recently published is the report of the Texas Eleemosynary Commission. This commission was appointed in 1923 to make a study of conditions existing in the greatly overcrowded state institutions for the insane, the mentally defective, the epileptic, the tuberculous, delinquent children, orphans and other dependent children. It was to direct attention particularly toward the prevention of mental disease, feeblemindedness, delinquency, and the increase of state dependents; the care and custody of the criminal insane; the revision of laws governing the commitment, parole, discharge, care and custody of inmates of state eleemosynary institutions. The report consists of three parts: 1, a preliminary report of the Commission, with recommendations to the Legislature; and, 2 and 3, the report of the mental hygiene survey of Texas made by the National Committee for Mental Hygiene under the auspices of the Commission.

* * *

Much publicity has been given by the press to the statement made by an English physician at a late meeting of the Royal Society that women have become much healthier since they have discarded heavy clothing. One of the illustrations given was that chlorosis has practically disappeared with the cessation of lacing and the wearing of tight corsets. But a new disease has appeared to take the place of chlorosis—a chronic indurative erythema of the legs of girls and young women, and it has been suggested that the cause of this disease is lack of protection of the lower legs, due to short skirts and thin silk stockings.

* * *

One of the recent biographies of President Washington states that when the great statesman had nothing else to do, he usually went out and counted something, then set it down on paper. He made inventories of farm implements, slaves, cubic contents of various things, furniture, logs, trees in various places, and carefully computed estimates of expenditures. He once even counted the number of clover seeds in a pound, and found there were 71,000.

* * *

A personality study of interest will be Albert Bigelow Paine's biography of Joan of Arc announced by Macmillan for publication the latter part of October. The author has endeavored to present the maid from the point of view, not of history, but of her contemporaries. Her trial is quoted verbatim, in so far as that is possible, all of Joan's known utterances are given, as well as the text of all her letters still extant.

* * *

Dean Roscoe Pound of the Harvard Law School, discussing the present campaign against crime and lawlessness in a recent issue of the Boston *Herald*, declares that we do not even know the extent of crime in this country. Our statistics are largely unclassified and very incomplete, in marked contrast to those of European cities. He states that our present judicial system was devised for a rural, pioneer, agricultural America, and applies very little and very ineptly to an urban, industrial civilization, and suggests the establishment of an endowment for scientific research into the whole question of crime and its causes, to take the place of "hysterical crusades." He characterizes lawlessness and the attempt to check lawlessness by strong arm methods as parts of the same social disease.

* * *

During the past fifty years there has been not only a decrease in the fertility of marriages, but also a decrease in the number of marriages themselves, according to Sir William Beveridge, writing in a recent issue of *Economica*. The changes he attributes to human purpose, and to birth control propaganda, and declares that our present problem is to find out how to apply the principle of birth control for the good of the race.

* * *

A new edition has recently been published by Doran of Oliver Day Street's book on Masonic symbols, entitled *Symbolism of the Three Degrees*. This forms volume three of the National Masonic Library, and this second edition is announced as rewritten and greatly enlarged.

* * *

An organization for the welfare of the physically handicapped in Minnesota has recently been formed as the Minnesota Conference for the Disabled. The objects are the rehabilitation of disabled persons, the correlation of activities concerning them, and the creation of an agency to receive and administer special funds for them.

* * *

Michigan state pharmacists have decided to ask the legislature of Michigan to permit drug store ownership to registered pharmacists only, the granting of pharmacists' registration to citizens only, and college of pharmacy graduation prerequisite to state board examination.—*Nation's Health.*

A list of floor plans of mental hospitals and training schools for the feebleminded has recently been issued by the National Committee for Mental Hygiene. The plans are listed both geographically and according to type of building.

* * *

Industrial Psychology is the title of new publication recently announced, of which Dr. Donald A. Laird of Colgate University will be psychological editor, and Percy S. Brown, works manager of the Corona Typewriter Company, head of the industrial board.

* * *

A bill has been passed in Louisiana requiring every male to pass a physical examination and to present a doctor's certificate showing that he is free from venereal disease before he can obtain a marriage license.

* * *

Some late British and foreign publications of interest to the medical profession are: *Health and Environment*, by Leonard Hill, M.B. (Arnold, London); *Sept Maladies de la Bouche*, by Dr. R. Nogue (Baillière, Paris); *Introduction to the Mind in Health and Disease*, for Students and General Practitioners Interested in Mental Work, by T. Waddelow Smith (Baillière, London); *Radiological Examination of the Male Urethra*, by G. L. S. Kohnstam and E. H. P. Cave (Bailliere, London); *Hemoptysis in Pulmonary Tuberculosis*, by Dr. Marc Jacquerod, translated by S. F. Silberbauer, M.D. (Baillière, London); *Aids to Surgical Diagnosis*, by Cecil P. G. Wakeley (Baillière, London); *Bilharzia*, a Paper for the Practitioner, by F. Gordon Cawston, M.D. (Bale, London); *Slit Lamp Microscopy of the Living Eye*, by Dr. F. E. Koby (Basle) translated by Charles Goulden and Clara Harris, M.B. (Lane, London); *Electrotherapy and Ionic Medication*, by H. H. U. Cross (Griffin, London); *The Stomach and Upper Alimentary Canal in Health and Disease*, by S. Izod Bennett, M.D. (Heinemann, London), *Treatment of Gonococcal Infection by Diathermy*, by E. P. Cumberbatch and C. A. Robinson, M. B. (Heinemann, London); *Chronic Disease*, a Working Hypothesis, by E. Bach, M.B. (Lewis, London); *Alcohol in Medical Practice*, by Courtenay C. Weeks (Lewis, London); *Preliminary Report on the Treatment of Interstitial Keratitis*, by R. Lindsay Rea, M.D. (Lewis, London); The Fats, by J. B. Leathes, M. B., and H. S. Raper, M.B. (Longmans, London); *Facts About Artificial Sunlight*, by Edwin L. Ash, M.D. (Mills, London); *Moralisings of a Medico;* being a mixed medley of many memories of medical student days in Edinburgh, by Adair Dighton (Step, London); *Chirurgie der Niere und des Harnleiters*, ein Lehrbuch, by Dr. James Israel and Dr. Wilhelm Israel (Thieme, Leipzig); and *Encouragement in Cancer Surgery*, by G. Grey Turney (Wright, Bristol).

Abstracts from Current Literature

PEDIATRICS

Spastic Bronchitis in Infancy and Childhood.—Kurt Ehle (*Monatsschrift für Kinderheilkunde,* April, 1925) abandoned the use of atropine sulphate and adrenalin chloride in spastic bronchitis of infancy and childhood because the results therewith were not very encouraging. His best results were obtained with urethan, which acts in two ways: by directly paralyzing the peripheral nerve endings of the vagus and by producing a central anesthesia and preventing muscular spasm by acting on the vagus centre. In the acute cases urethan is unequalled.

The first symptom is restlessness. There is an expiratory stridor, the facial expression is anxious and the head is retracted. The anterior margin of the lung is generally at the costal arch and the posterior at the eleventh or twelfth rib. The clinical picture is one of bronchotetany.

The author uses a dose greater than that usually recommended. Up to four months of age he gives 0.3 to 0.5 gm. by mouth, or 0.8 to 1.0 gm. by enema; from four to six months of age he gives 0.6 to 1.0 gm. by mouth, and 1.5 gm. by enema; from seven to twenty-four months of age, he gives 1.5 gm. by mouth and 2.0 gm. by enema. If necessary, two thirds of these doses may be repeated after half an hour. Small doses of bromine are also useful. It reduces central excitability. The prophylaxis includes the avoidance of all unnecessary excitement and disturbance.

Rheumatic Infection in Childhood: The Subcutaneous Fibroid Nodule as an Early Manifestation.—It has been stated that subcutaneous rheumatic nodules usually appear only in grave affections associated with gross cardiac disease. Arguing, however, on analogy with the findings in adults suffering from fibrositis, it did not seem improbable that nodules less obvious than those of graver infection might be discovered in subacute cases. When this suggestion had been established in part by the examination of children known to be suffering from rheumatic infection, Vincent Coates (*British Medical Journal,* March 21, 1925) examined one hundred consecutive children between the ages of two and twelve years very carefully for subcutaneous nodules irrespective of the complaints.

In searching for the nodules particular attention was paid to the spinous processes of the vertebræ and to the olecranon process. The nodules appeared to vary in size from a small sago grain to that of a pin's head, and were often in small clusters. Synovitic creaking was often obvious round the vertebral spines and is most characteristic. Of the one hundred children, twenty-three gave a history suggesting rheumatic infection, and in these no other causes of a toxic state could be elicited except Ascaris lumbricoides in two instances, efficient treatment of which did not alleviate the symptoms.

Significance of Colloid Reactions in the Cerebrospinal Fluid in the Diagnosis of Nervous Diseases in Childhood.—Alfred Marchionini (*Monatsschrift für Kinderheilkunde,* April, 1925) states that according to the examination of the cerebrospinal fluid with the normomastic reaction in eighty cases of nervous diseases in childhood, the colloid re action has a not inconsiderable significance. This reaction shows three types of curves: a normal, a luetic, and a meningitic curve.

The finding of a normal curve—the absence of precipitation—shows definitely that a luetic process in the central nervous system, which leads to pathological changes in the cerebrospinal fluid. does not exist (excluding the neuroluetic etiology in idiocy, imbecility, epilepsy, etc.). It also makes it possible to differentiate sharply between meningismus and acute toxic hydrocephalus, on the one hand, and tuberculous meningitis and purulent meningitis, on the other, because the former group never, and the latter always, produce a pathological change in the colloid curve.

The luetic curve, characterized by flocculation on the left, indicates a luetic process in the central nervous system. The nature of this process, whether general paralysis, tabes dorsalis, cerebral syphilis, or syphilitic meningitis, cannot be definitely recognized from the colloid curve alone; a differential diagnosis can be made only in conjunction with the history and cliniconeurological findings. The colloid reaction is more delicate than the Wassermann reaction in the cerebrospinal fluid; it appears earlier and disappears with the recovery later than the Wassermann reaction. The diminution in the breadth and depth of the curve may give prognostic indications in the sense of a cure in treated cases of nervous syphilis.

The meningitic curve, characterized by flocculation on the right, definitely indicates a suppurative or tuberculous meningitis. Tuberculous meningitis shows a slight flocculation (+) in one or two tubes, whereas the suppurative type shows an intensive reaction (+ + or + + +) in three to five tubes. The possibility of a prognostic evaluation of the meningitic curves has not as yet been proved. In many cases the cerebrospinal fluid shows luetic curves in multiple sclerosis, epidemic encephalitis, and in acute anterior poliomyelitis.

Irradiation of Milk and the Healing of Rickets.—S. J. Cowell (*British Medical Journal,* March 28, 1925) tested the efficacy of irradiated children's food as a promoter of the calcification of bone. Three young children with active rickets, as determined by radiographic examination of their wrists, were given a diet, which was not in itself calculated to promote particularly rapid calcification of their bones. One pint of milk in the twenty-four hours was given them, and this was virtually the only source of antirachitic vitamine in their diet. The milk destined for two of the children was exposed to the rays of a mercury vapor lamp of the Hanot type before it was given to them, while the third child received untreated milk. The irradiation was carried out twice a day by exposing the milk in a wide shallow dish for twenty four minutes at a distance of three feet from the lamp. At the end of four weeks the children's wrists were again roentgenographed. It was plainly visible that in the case of the child that received untreated milk there was during the month only a slight increase in the amount of calcification at the lower ends of the radius and ulna, while in the case of the two children that had received milk that had been exposed to ultraviolet rays dense calcification had taken place, much in excess of what one would expect to have occurred in this short time as the result of giving this particular diet.

This quite definite and remarkable "activating" effect of ultraviolet rays on foodstuffs is obviously well worth following up, and opens up new possibilities in the treatment of infantile disorders.

Throat Infections in Children.—Joseph Brennemann (*Archives of Pediatrics,* March, 1925) states that the diagnosis of throat infections in children is usually easy but by no means always so. It is usually based on one or all of the following conditions:

1. The history of a cold, cough, or sore throat. All of these may be absent. It must always be remembered that young children only exceptionally complain of sore throat.

2. Examination of the throat itself. Early this rarely leaves much doubt, commonly none if one is accustomed to the appearance of the normal throat. It is often of distinct value in diagnosis to recognize the peculiar type of throat that is prevalent at the time. Spots on the tonsils must never be considered a desideratum, as in infancy a follicular tonsillitis is a rarity and in early childhood it is relatively infrequent. The younger the child the more surely is the whole throat and nasopharynx involved.

3. The fact that there is an epidemic and that the present case has some of its characteristics.

4. The fact that other members of the family are afflicted with the disease in a more evident manner than is the child himself. This is often of great value in doubtful cases.

5. The fact that certain complicatoins exist that occur with nothing else. An otitis media, an acute cervical adenitis, a cough, a laryngitis, tell one unmistakably that we have or have had a throat or nasopharyngeal infection, no matter how normal the throat may appear at the time of examination. Conjunctivitis, gingivitis, arthritis, pyelitis, petechial hemorrhages are not pathognomonic but strongly suggestive, especially at certain times.

In the differential diagnosis only one thing must be emphasized. It is almost the rule that these cases, unless there is an evident pneumonia, are called "intestinal trouble." Especially is this true of those cases in which there is vomiting and diarrhea, but it is also true of those with protracted fever

in which there is no outstanding evidence of an upper respiratory tract infection.

All of these infections are, of course, contagious and should be treated as such. Isolation in the family is useless unless immediate, complete, and prolonged. The possibility of building up the individual resistance to autoinfections, to catching cold from chilling, exposure, etc., must be thought of. Vaccine therapy is not yet of much value. Hardening with cold baths, outdoor life in nearly all kinds of weather, moderate clothing, and care in the avoidance of chilling, wet feet, etc., doubtless have good effect. In this country this effect is largely nullified by overheated living quarters. Adenoidectomy is of undoubted value at any age, in mouth breathing, in repeated infections, in insidious deafness, in facial and palatal distortion, in nocturnal restlessness and resulting stupidity, nervousness, poor appetite, and malnutrition. Opinion is still divided regarding the value of tonsillectomy. However, it must be remembered that the tonsil is not the atrium of infection nor does it bear the brunt of it, in young children, and especially not in infants.

The paramount indication in every case that has any fever is rest in bed, till at least a day or two or more after the temperature is normal. Salicylates have a beneficial effect if given in large doses, say a grain for each year every three or four hours. No local treatment is indicated except a bland oily substance, perhaps containing menthol, to clear the nostrils in babies; or a steam inhalation of benzoin and oil of eucalyptus, or wet compresses about the throat or chest for persistent cough. Temperatures above 104° require the initially tepid pack kept wet with cooler water.

Rat Bite Fever in an Infant.—Leon H. Dembo, H. O. Ruh, Warren C. Fargo and George R. Taylor (*American Journal of Diseases of Children,* February, 1925) report a case of rat bite fever in an infant aged seven months, in which the clinical picture was essentially the same as that described by other authors. The Spirochaeta morsusmuris was recovered from serum taken from the bite wound, by examination under dark field illumination. Recovery took place under sulpharsphenamin therapy, three injections, each of 0.05 gm. sufficing.

Prophylaxis is best accomplished by complete cauterization of the wound as soon as possible after the bite. Pure phenol is the best agent, and this should be supplemented by wet dressings of a mercuric chloride solution (1: 3000). The injection of a five per cent. phenol solution about the wound has been recommended. Arsphenamine, neoarsphenamine or sulpharsphenamine act specifically. Many of the cases reported have cleared up after one injection, while protracted cases eventually yield to repeated injections. Therapy along other lines is largely symptomatic. The opiates, acetyl salicylic acid or acetphenetidin may be administered to relieve the muscular pains. Fever may be partially controlled by tepid sponging and the judicious use of coaltar products. The diet should be light and nutritious. During convalescence, bitter tonics or an iron and strychnine combination are valuable aids.

Weak and Flat Foot in Children.—Samuel W. Boorstein (*Archives of Pediatrics,* March, 1925) draws the following conclusions:

1. Weak feet and foot strain are present in children though not to the same extent as in adults and should be treated before disastrous results ensue.
2. The predisposing causes are general weakness, excessive weight, rickets and contracted tendo Achillis.
3. The direct cause is disproportion between the strength of the foot and the strain to which it is subjected.
4. The symptoms of weak feet in children are deformity, tired feeling when walking, and occasionally pain.
5. The proper shoe from early childhood is a very important item as a preventive of future disability.
6. The child should be instructed to stand and walk properly, viz., the feet parallel or even slightly turned in.
7. The causing factor, as knock knees, etc., must be remedied so as to prevent recurrence of the foot disturbance.
8. The acute foot strain should be relieved by rest and adhesive plaster strappings.
9. The flexible weak feet are treated by strappings and exercises.
10. The short tendo Achillis should be lengthened either by stretching or open operation.
11. If the case is severe a metal support may have to be prescribed but this must be constructed scientifically so that the child should not depend permanently on this support.

Splenomegaly in Infants and Children.—Thomas E. Buckman (*Medical Clinics of North America,* March, 1925) states that practically every case of enlarged spleen can be placed in one of four groups, namely, the acute infectious group, the tumor group, the hemolytic jaundice group, and the cirrhosis group. It is often difficult if not impossible to decide in the present state of our knowledge the exact diagnosis in a given case, but it is usually possible to tell whether the underlying condition is fundamentally an acute infection, a tumor, hypersplenism, or a cirrhosis. Removal of the spleen is, of course, contraindicated when the cause of the enlargement is an acute infection. Except in the case of Gaucher's disease splenectomy should not be performed if the cause of the splenomegaly is a tumor in the sense here used. On the other hand, benefit is to be expected from splenectomy in hemolytic jaundice and in cirrhosis of the spleen whatever the cause. It has been said that splenectomy should be done in every case in which an enlarged spleen persists unless an internist can show cause why the spleen should not be removed. The burden of proof is put on the internist. The author agrees with this attitude, but it is important to remember that the internist can often show cause why the spleen should not be removed.

Studies on the Carbohydrate Metabolism of Infants.—Frederick F. Tisdall, T. G. H. Drake, and Alan Brown (*Journal of Laboratory and Clinical Medicine,* June, 1925) explain a procedure for blood sugar determination based on the Shaffer-Hartman method which requires only 0.2 c.c. of blood. Twenty approximately normal infants showed an average fasting concentration of blood sugar of 0.087 per cent. In twelve cases of marasmus the average concentration was 0.070 per cent. Values as low as 0.050 per cent. were obtained in the latter group. When five, ten, and fifteen per cent. solutions of glucose are given interstitially to normal infants, the blood sugar curve reaches its height about half an hour after the injection is given. This rapidity of absorption is of practical value when an intravenous injection cannot be given readily. The rise in blood sugar concentration in normal infants is more marked after the interstitial injection of ten per cent. glucose than after the interstitial injection of five per cent. glucose. The fall in the blood sugar curve after interstitial injections of glucose occurs with remarkable rapidity. The intravenous injection in normal infants of large amounts of glucose, i. e., one gram of glucose to the pound of body weight, is followed by a rapid diminution of the blood sugar concentration, after the preliminary rise. One hour after injection, the concentration may be actually less than that found before the injection. Infants with conditions such as acute intestinal intoxication and fermentative diarrhea are unable to utilize glucose introduced parenterally with the same rapidity as normal infants. Attention is again directed to the tremendous ability of the normal infant to utilize glucose introduced parenterally.

Association of Anemia and Pneumonia in Infants; Treatment by Blood Transfusion.—Ten cases of pneumonic infections occurring in anemic infants are described by Murray H. Bass (*American Journal of Diseases of Children,* March, 1925). All of these were treated by means of human blood transfusions. The results show that the addition of the new blood was accompanied not only by improvement in the anemia but in the cure of the infection, in some cases in a manner similar to a crisis. Nine patients recovered. One patient suffering from celiac disease with secondary infection, improved considerably for a time but finally died of purulent meningitis.

Blood transfusion is advised as being helpful in the treatment of anemic infants and young children, especially when the anemia is complicated by pneumonia. It is not being urged as treatment for pneumonia but as a cure for the anemia, as a result of which the pulmonary infection is apparently checked. Heretofore pneumonia has been considered a contraindication to blood transfusion, but in the author's experience the opposite is the case, for when a child with severe anemia is stricken with a pulmonary infection, the chances for recovery seem to be greatly increased by the use of transfusion.

There is apparently a definite rationale for the employment of blood transfusion, during the course of certain cases of anemia with complicating pneumonia. The pneumonia in such cases should be considered not as a contraindication to the use of transfusion, as heretofore, but as a distinct indication for such treatment.

Fibrosis at the Base of the Lungs in Children.—Kenneth H. Tallerman (*Archives of Pediatrics,* March, 1925) states that an increase of fibrous tissue at the base of the lung consequent upon measles and acute pulmonary infections is far from rare in children. It appears to be secondary to an inflammatory condition in or around the alveoli and bronchioles, and probably also to pleural involvement. The condition is sometimes confused with tuberculous disease of the lung, but the rarity of this latter as a chronic illness in children, the difference in symptomatology, and the general position of the process, should sufficiently distinguish the two. The roentgenogram is of assistance and shows an increase of shadow extending from the hilus outward and down toward the diaphragm, the edge of which is likely to appear blurred. Associate changes noted in the plate are usually peribronchial thickening with some hilus gland enlargement. The definite mottling seen in fibrocaseous tuberculosis is conspicuous by its absence, and the shadow is not that seen in pneumonic consolidation. The condition may be the starting point of a bronchiectasis, the earliest evidence of which is given by the symptoms of foul sputum and offensive breath added to a picture clinically and radiologically one of fibrosis. The prognosis depends upon whether the process is arrested or whether a reinfection, a gradual extension of the fibrosis, or the supervention of a bronchiectasis should take place.

The treatment is along general and dietetic lines, aiming at improving the resistance and nutrition of the child. All sources of focal infection must receive adequate attention.

Protein Sensitivity in Infantile Eczema.—Franklin J. Corper (*American Journal of Diseases of Children,* March, 1925) finds that when one compares the results obtained in cases of true infantile eczema with those obtained in true cases of food idiosyncrasy, one is impressed by the fact that in the idiosyncrasies a positive reaction is practically always obtained to those foods causing manifestations. This may be explained on the assumption that in such cases there is an extremely low tolerance or threshold for the food giving rise to symptoms, while in eczema the infant may have a limited tolerance to single proteins or to a combination of proteins. Or it is quite within reason to suppose that eczematous infants suffer from the cumulative action of such proteins, to which there is sensitivity only in degree. That specific proteins are the sole etiologic factors in the production of eczema is yet to be proved, and most certainly the proof offered up to the present is insufficient on which to base conclusions. That, however, positive cutaneous tests are associated with infantile eczema is beyond question, but at present we must regard this relationship as a guide to diagnosis and treatment and as a possible stepping stone to the discovery of the actual etiology.

Infants with eczema show a high percentage of positive skin tests to proteins, which may or may not be included in the dietary. Elimination of the specific proteins is conducive to subsidence of symptoms in only a relatively small percentage of cases. Improvement of clinical manifestations, rather than complete recovery, may be expected in those patients who are benefited. Patients sensitive to animal proteins are more likely to respond to specific treatment than those sensitive to cereals, fruits and miscellaneous proteins. The presence of a positive cutaneous test is not a criterion to the successful treatment of infantile eczema.

The Scorbutic Diathesis.—H. L. Ratnoff (*Archives of Pediatrics,* March, 1925) states that the chief etiological factor in the production of scurvy is lack of vitamine C, but in addition to this there must be other factors working in conjunction with it, before the true clinical picture of the disease can be produced. These are: 1, age, which is six months or over; 2, constitution, some children requiring but small quantities of vitamines and therefore do not develop scurvy, even when vitamines are not given in sufficient quantity; 3, infection, the greater the number of infections which a child undergoes, the more will the tendency to develop scurvy be increased. Only when all these factors work in conjunction will scurvy be produced, and therefore it may be regarded as a chronic disease.

The actuality of a scorbutic diathesis can be demonstrated by the appearance of petechiae or the application of the capillary resistance test. When this diathesis exists, the proper stimulus, toxic or mechanical, is able to produce active scurvy, and the fact that the disease is recurrent is one of the best demonstrations of the existence of such a diathesis.

As soon as any hemorrhagic evidences appear—and the possibility of hemophilia, purpura, etc., has been excluded—orange or lemon juice, or that of tomatoes, two to four tablespoonfuls a day, should be given. If the scorbutic diathesis is only possible or suspected, all children who fail to grow or gain properly when arriving at the age of six months or over, or show a marked susceptibility to infection, should likewise receive additional feedings of vitamine C. The body of every bottle fed infant should be fortified against the possibility of developing the scorbutic diathesis by the addition of moderate quantities of this element to his food during this period. Should the premonitory symptoms escape attention and the child be permitted to develop a severe and dangerous form of the disease, large quantities of vitamine C must be at once introduced into the dietary. As there is always a possibility of a recurrence, it is best to continue the administration of vitamine C as recommended, for at least three months after there has been apparent cure. Only when the child is steadily gaining in weight and body length; is fully resistant to infection without any recurrence of scorbutic symptoms; when the appetite is good and the disposition happy and contented; then only can we feel assured that the scorbutic diathesis is fully conquered.

Bronchial Asthma and Chronic Bronchitis in Children.—Ralph H. Kuhns (*Archives of Pediatrics,* February, 1925) states that the treatment of bronchial asthma and asthmatic bronchitis depends upon the particular type of offending protein or bacteria. Another method of treatment is that of the acute attack, and the general treatment of the disease.

In treating the acute attack, mustard plasters applied to the thorax will often relieve the spasm sufficiently to reduce the respiration. Adrenalin chloride given hypodermically is also a useful drug to combat the severe dyspnea. Many physicians also give antipyrine of bromides at bedtime in the hope of avoiding or lessening the severity of the nocturnal attacks.

The general or interval treatment of these patients recommended is the following: 1. A careful history of the child's present and previous illnesses should be taken, investigating also the illnesses of parents and near relatives having any bearing on the condition. 2. A complete physical examination of the child should be made, investigating the ethmoid region of the nose and other accessory nasal sinuses. 3. Laboratory examinations as follows: blood count, urine examination and roentgenograms of the chest. 4. Protein skin tests to determine the offending protein. 5. Theatment of the ethmoid region of the nose by a rhinologist by means of infiltrating the submucous tissues of the nose and ethmoid regions with an antiseptic solution according to the method of Haseltine. 6. The administration of calcium according to the method of Pottenger, for the following reason: inasmuch as the activity of the vagus nerve, which belongs to the parasympathetic system, is antagonized by the sympathetic nerves, and inasmuch as a relative increase in the calcium ions produces the same effect as sympathetic stimulation, the administration of calcium is a rational therapeutic measure in combating asthmatic paroxysms. 7. The exposure of the body to the ultraviolet rays of a mercury vapor quartz lamp for the following reasons: Novak and Hollander in a series of patients found the calcium content of the blood serum to be low in hyperesthetic rhinitis, hay fever and asthma. They also state that there is evidence of metabolic change in the animal body brought about by solar rays in the fact that the inorganic phosphate was brought up to normal by sunlight and also carbon arc irradiation. A similar effect was had with calcium in the blood. The ultraviolet light seems to be necessary for the normal metabolism of the infant. Exposure to the mercury vapor quartz light, together with combined calcium thyroid therapy, appears to fix permanently the ionic calcium content of the blood stream. The lamp is raised about one meter from the patient and fractional body exposures are made two or three times weekly or oftener. The time of exposure, at first two minutes, is increased at each treatment by from two to three minutes, depending upon the tolerance of the individual. At each successive treatment the distance between patient and lamp is decreased by three inches. The smallest distance reached is about eighteen inches, while the longest exposure made may reach fifteen minutes, or in exceptional cases, when the tolerance of the individual is great, twenty minutes. 8. Treatment by means of autogenous vaccines containing all the organisms grown from the nose and throat cultures.

DIABETES

Renal Threshold for Glucose in Diabetes Associated with Nephritis.—Ten cases of diabetes associated with renal disease are reported by E. Wordly (*Lancet,* March 28, 1925), in all of which there was present a marked inability to concentrate urea as judged by MacLean's urea concentration test. In eight of these ten cases the renal threshold for glucose was normal in spite of the inability of the kidney to concentrate urea. In two cases the renal threshold for glucose was raised, in one case slightly, in the other to a greater extent. It would appear, therefore, that chronic nephritis of the azotemic type does not, in the majority of cases, alter the permeability of the kidney for glucose. In addition, these observations show that MacLean's urea concentration test is of greater value in estimating the function of the kidney in diabetes than an estimation of the blood urea, since the prolonged period during which many of the patients have been kept on a low diet tends to lower the blood urea. It is, of course, well known that it is possible, in cases of nephritis, by giving a diet containing very little protein, to reduce the blood urea, when previously on a full diet, it had been very high, to an almost normal figure.

Treatment of Diabetes by Raw Flesh Gland (Pancreas).—Thomas J. Hollins (*British Medical Journal,* March 14, 1925) believes that in spite of the many theoretical objections to the use of raw pancreas by the mouth in the treatment of diabetes mellitus, it seems to do all that insulin does, at the same time being free from the grave risks attendant on the use of insulin (for example, hypoglycemia). The facts collected by the author seem to point to the direction of raw pancreas being a complete substitute for insulin. It renders the urine free from sugar within twenty-four hours of the initial dose; it lowers the blood sugar, and the ketone bodies disappear from the urine. If in the course of the routine administration of raw pancreas the gland is withheld, the sugar constantly reappears in the urine.

The method usel in the administration of raw gland is as follows: The patient is first carefully dieted and kept at rest. If this fails to clear the sugar from the urine he is at once given raw gland and a diet arranged according to his weight and the type of work he has to do. The first essential is that the gland should be perfectly fresh. After keeping and heating the gland is useless. It seems probable that the internal secretion of the pancreas is a labile substance easily destroyed and rendered inert by heating and keeping. It must be given raw, and is best given finely minced. The dose recommended is one tablespoonful daily. Glands of the sheep, ox, or pig may be used. It forms quite a delicious meal, especially when taken with lettuce, and patients easily get accustomed to it and even like it.

New Method of Treating Diabetes Mellitus and Associated Disturbances of Metabolism.—Hugo Weiss (*Wiener klinische Wochenschrift,* October 30, 1924) renders a preliminary report on and recommends for further trial a remedy called "lethizit," which is a white powder soluble in water, a complex alkaline double salt of lithium and sodium, which are combined with citrate ($Li_2C_6H_7NaO_7 + 2H_2O$ in the three carboxyl groups of citric acid the hydrogen atoms are displaced by lithium and one by a sodium atom). This powder was found to be entirely harmless and is based on the principle of making every appearing form of uric acid soluble and ready for excretion and thereby eliminating also the chemical sequelæ. If diabetes mellitus is considered to be a secondary phenomenon of uric acid metabolism, an effect upon the uric acid mechanism must also have a regulating effect upon the metabolism of sugar.

A series of forty cases were studied, including only old cases that had been repeatedly treated before. In the beginning the powder is given in daily doses of two grams, dissolved in one third of a glass of water, after the noon or evening meal. After seven days the dose is increased to three grams, possibly even to four grams. The amount of carbohydrates in the food may be increased simultaneously with the increase in dose. After the disappearance of the glucose from the sugar, the treatment must not be interrupted, only the dose may be diminished until one is certain that the carbohydrate tolerance is sufficiently high. The duration of the treatment lasts an average of two to three months, sometimes a little longer. Control of the urine is absolutely necessary, because occasionally the treatment must be repeated.

The author draws the following conclusions: 1. Most of the cases of albuminate and carbohydrate metabolic disturbances may be favorably influenced by the lethizit treatment of Szirmay. The amount of the sugar excreted diminishes rapidly and sometimes disappears entirely, even in cases that could not be influenced before that by diet or by insulin treatment. 2. The patients can take carbohydrates often in large amounts and assimilate them without showing any increase of the sugar content in the urine. The difficulty of feeding these patients is done away with by the omission of a strict diet or fast days. 3. Acetone, diacetic acid and b-oxybutyric acid disappear in a very short time. 4. The body weight is increased even in severe cases as a result of the extensive utilization of the food. 5. This remedy has the great advantage that it is given by mouth and that it gives better results than former methods of treatment.

Use of Intarvin in Diabetes Mellitus.—D. Murray Lyon, W. Robson and A. C. White (*British Medical Journal,* January 31, 1925) claim that further investigations are needed before the claims on behalf of this fat can be fully substantiated. In the cases recorded by these authors no reduction, but rather an increase, in the amount of acetone in the blood followed the administration of intarvin. The rise, however, is less than when an equivalent quantity of other fat is added to the diet. The respiratory quotient did not at any time give indication of more carbohydrate than usual being burned under the influence of intarvin, as might be expected if the acid ultimately broke up to form sugar. On the other hand, the addition of intarvin to a stabilized diet always led to the excretion of small traces of sugar in the urine. The changes in the blood fat under intarvin cannot as yet be explained. When a patient's diet has been stabilized at his maximum tolerance, one hundred grams of intarvin can be added (allowing about seven hundred extra calories) without the appearance of clinical signs of acidosis. But in view of the conflicting figures obtained regarding the control of ketosis consequent upon its use, intarvin cannot be used indiscriminately to build up diets to a maintenance level without fear of ketosis.

The Possibilities of Insulin in General Practice.—Reginald Fitz (*Boston Medical and Surgical Journal,* March 19, 1925) discusses this subject at considerable length and closes with these remarks:

Insulin is a well established aid in the treatment of certain cases of diabetes. Since the majority of diabetic patients in this country depend upon their family doctor for treatment, general practitioners must know how and when to use insulin.

Diabetes tends to be a mild disease and only about one third of the cases ordinarily seen need insulin. Undernourished diabetics, young diabetics, diabetics with a surgical complication and diabetics with acidosis or an acute infection usually need insulin, while elderly and obese diabetics do not.

Methods have been developed for simplifying the treatment of diabetes. At present there is a tendency for too many diabetics to be sent to hospitals for education and treatment. Patients can now learn readily how to calculate diets, how to measure and prepare them, how to test the urine for sugar and how to administer insulin. Insulin affords a rapid method for desugarization. Selected cases can be intensively treated with insulin, so that a satisfactory therapeutic result can be accomplished in a few hours instead of in a few days or weeks. Attempts should be made to shorten the period of hospital treatment for diabetics because of the expense of treatment in the first place and so that the available hospital beds for diabetics can be used by sick and needy patients who require bed and special nursing care.

Coma is the chief diabetic emergency which the general practitioner is called upon to treat. Coma tends to occur in young people more frequently than in old people. It may begin acutely without known antecedent symptoms of diabetes; it can usually be prevented by properly trained diabetics. The physical signs of coma are important in the early diagnosis and there must be manifestations of acidosis and glycosuria to justify the diagnosis. Coma must be treated as soon as possible after the diagnosis is established for the longer the duration of coma before treatment is instituted the worse the prognosis. Coma cases with infection, those in shock, and those with very high blood sugar concentrations have a poorer outlook than those without demonstrable infection with a well sustained blood pressure and without tremendous hyperglycemia. The treatment of coma is simple and satisfactory. Large doses of insulin, plenty of fluid and good nursing care are the essentials.

Severe Acidosis of Diabetes.—John H. Musser, Jr. (*Medical Clinics of North America,* November, 1924) discusses the proper management and handling of a case of threatening or developed coma. Patients who are unable to afford proper nursing care at home should be removed to the hospital at once where they should be put in bed, kept warm, and kept as quiet as possible. The bowels should be kept moving daily by the use of enemas. Cathartics may cause diarrhea which is likely to increase the acidosis. If the pulse is weak, the patient has considerable shock, he should be given digitalis and caffein. Liquids should be forced—1,000 c.c. every six hours at least, preferably in the form of hot tea, coffee, or broth.

If the patient is completely unconscious usually the preliminary dose of insulin will bring him out of his unconsciousness. He should be given twenty grams of glucose by mouth, which may be given in the form of cane sugar or syrup. The first dose of insulin should be at least fifty units. If the person is absolutely comatose the insulin should be given intravenously in a five per cent. glucose solution. In the private home it is usually enough to give five per cent. solution of glucose by bowel and the insulin hypodermically. Depending on the response of the patient the glucose should be forced or diminished, and the same may be said of the insulin. The wise rule is to continue giving the glucose fifteen grams hourly and the insulin ten to forty units every third hour unless the sugar disappears from the urine. When consciousness returns, the patient should be started on a diet high in carbohydrates in order to overcome the ketosis. As soon as the urine becomes free of diacetic acid the carbohydrate is reduced and the subsequent treatment is that of any case of diabetes.

Muscular Exercise in Diabetes Mellitus.—K. S. Hetzel (*British Medical Journal,* January 17, 1925)) summarizes his findings as follows:

1. Muscular exercise in patients suffering from diabetes mellitus depletes the blood glucose provided there is an adequate supply of insulin in the tissues.
2. The more perfect and complete tissue metabolism is demonstrated by the disappearance of ketones from the urine under these conditions.
3. As the result of exercise the blood sugar tends to fall rapidly to between 0.07 and 0.10 per cent., but it does not become lowered further.
4. No hypoglycemic reactions have occurred on exercise even if the initial blood sugar was as low as 0.07 per cent.
5. Muscular exercise does not tend to cause acidosis provided there are adequate carbohydrate and insulin for its transformation.
6. Exercise in patients without sufficient insulin, endogenous or exogenous, causes no change in the concentration of glucose in the blood, but markedly increases the production of ketone bodies, with resultant acidosis and the likelihood of the supervention of a diabetic coma.
7. An hypothesis for the action of insulin is suggested, namely: Insulin is essentially associated with the metabolic processes in the muscles, but apparently it is not necessary for the transformation of glycogen to lactic acid in the contraction of muscle, but the transformation of glucose into glycogen precursors and the intrinsic metabolic processes of muscle depend on its presence.

Diabetes and Coma.—William P. Murphy (*Medical Clinics of North America,* March, 1925) draws the following conclusions from a study of five cases of diabetes and coma:

The onset of acidosis with resulting coma may be very acute and may be precipitated by an infection, by gross dietary indiscretions, or by failure to follow out the details of diabetic treatment. The carbon dioxide combining power of the blood is a better indicator of the degree of acidosis than is the urinary diacetic acid reaction. It is possible that other acids than the ketones may help to produce acidosis in diabetes. This fact probably explains the small amount of diacetic acid demonstrable in the urine of certain of the cases with severe acidosis. It is important to know whether or not alkali has been administered in those cases in which carbon dioxide combining power of the blood and the diacetic excretion in the urine are both high, and it is dangerous to make the diagnosis of diabetic coma in cases without a lowered alkali reserve. There is usually a relatively high red and white cell blood count in coma cases. The blood changes are probably due to the dehydration, which may be marked in acidosis.

The following are a few practical details which may be of value in managing diabetes with severe acidosis or coma:

1. Obtain a sample of urine and examine it for sugar and diacetic acid at the earliest possible moment.
2. If large amounts of sugar and of diacetic acid are present treatment for diacetic acidosis should be started immediately, regardless of the presence of complications.
3. Treatment may be started in the home. The patient should be kept warm. An enema should be given. In the early stages of coma the patient can usually be aroused enough to take small amounts of fluid by mouth. Small rectal injections are easily given. Insulin should be given subcutaneously, beginning with 10 to 20 units, depending upon the amount of sugar and diacetic acid found in the urine. The effect of insulin can be safely observed by repeated urine analyses. Blood tests are not necessary.
4. The burden of the diagnosis and treatment of diabetic coma rests with the physician who first sees the case. All doctors should carry an ampule of insulin as part of their emergency outfit.

Diabetes.—At the Canadian Congress of French Speaking Physicians A. Rousseau (*Revue Française d'Endocrinologie,* March-April, 1925) presented an extensive study of diabetes in the light of the discoveries of recent years. He emphasized the rôle of the liver and the pancreas in producing the disturbances of glycogenic and glycolytic function incident to diabetes. In his view simple diabetes is due most of all to an alteration of hepatic glycogenesis with secondary pancreatic effects, while severe diabetes is the consequence of a primary alteration in the pancreatic internal secretion. In addition to heredity, superalimentation, and sedentary habits as the common causes of diabetes, an important place must be assigned to infection and to toxic infection of gastrointestinal origin. The aim of all treatment of diabetes is to diminish hyperglycemia and glycosuria, in view of the existing degree of carbohydrate tolerance, without provoking acetonuria. Diet and rest are the basis of treatment. Insulin is indicated chiefly when a balanced ration is impossible, but is always an emergency resort.

Studies of the Action of Insulin on Different Carbohydrates.—Insulin, says J. Enselme (*Thèse de Lyon,* 1924), appears to be the prime factor in regulating carbohydrate metabolism. He finds that *in vitro* its effect on different carbohydrate solutions, whether alone or in presence of blood serum, is completely negative. In contact with various normal blood ferments it increases the action of maltolytic ferment, affects glycolytic ferment variously, and remains wholly inactive in relation to ferments destructive of dextrine and glycogen. The addition to these different sugars and solutions of organic tissues such as liver and lung or of phosphorus compounds in no way modifies the effect of insulin upon them. It seems, therefore, that the cause of insulin hypoglycemia does not reside in the blood.

Treatment of Diabetic Xanthoma with Insulin.—A. Chauffard, P. Brodin, and R. Yovanovitch report (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris,* November 14, 1924) their observations on a man of fifty years, a diabetic affected for more than a year by nodular xanthoma of the wrists, knees, and ankles. He exhibited blood hypercholesterinemia and increase of neutral fats in the blood. After a month and a half of treatment with insulin the xanthoma almost wholly disappeared and at the same time a considerable modification took place in the blood chemistry. The insulin acted not only on the carbohydrate metabolism, but quite as much on the fat metabolism.

Insulin Deprived of Toxicity.—By a special method C. Piazza (*Revue Française d'Endocrinologie,* March-April, 1925) has obtained an active insulin devoid of toxicity. The toxic phenomena following the use of Banting's insulin are not due to hypoglycemia, but to the toxicity of the insulin itself. Piazza's insulin is thermostabile, can be sterilized, and is administered by weight.

Effect of Insulin on Pneumogastric Excitation.—Garrelon and Santenoise (*Comptes Rendus de la Société de Biologie,* 1924) found insulin to be one of the most powerful stimulants of the vagus, increasing the oculocardiac reflex and slowing cardiac action. Vagus hypertonia appears after a variable period of time, depending on the strength of the preparation and the amount injected. It is delayed by the presence of albumen. This hypertonia is long continued, lasting three or four hours, sometimes more, and corresponding closely with the modifications of glycemia.

Insulin.—A. Leger calls attention (*Revue Française d'Endocrinologie,* March-April, 1925) to the fact that insulin does not merely affect carbohydrate metabolism, but also that of fats and albumens. The only contraindications to its use are renal diabetes and simple diabetes where dieting proves effective. In diabetes the indications are, first, simple cases where the coefficient of carbohydrate assimilation is low; second, severe or tuberculous diabetes and especially infantile diabetes, and third, diabetes complicated by infection, gangrene, tuberculosis not too far advanced, and where surgical intervention is demanded. Apart from diabetes, insulin is indicated for acidosis from pregnancy, cyclic vomiting in infants, and similar causes.

Insulin: Its Intradermal Injection.—Ernst F. Müller and H. B. Corbitt (*Journal of Laboratory and Clinical Medicine,* June, 1925) found in rabbits that intravenous injections of insulin are the least effective, subcutaneous injections are considerably more so, and the intradermal mode of administration is by far the most effective means of giving it. The degree and the period of effectiveness do not depend upon the rapidity of resorption, but upon a hitherto unknown factor, probably related to the action of the involuntary nervous system. This property seems to be inherent in the skin rather than in the subcutaneous tissues or in the body fluids.

Glycolytic Effect of Amygdalin.—Livierato (*Revue Francaise d'Endocrinologie,* March-April, 1925) considers tonsillar extract superior to insulin in the treatment of diabetes. Glycemia diminishes rapidly and acetone disappears at the same time that the toxic phenomena are relieved. All the complications of diabetes are successfully overcome by this method.

SYPHILIS

Treatment of Syphilis with Bismuth.—J. L. Grund (*Boston Medical and Surgical Journal,* February 19, 1925) says that the superiority of bismuth over mercury, both in spirocheticidal and serological aspects, are plainly evident. Milian in this regard places it midway between the arsenicals and mercury and compares the theraputic activity of arsphenamine, bismuth, and mercury in the following manner: the therapeutic activity of arsphenamine is represented by the figure 10, that of bismuth by 7 and that of mercury by the figure 4. With this in view, bismuth must be seriously considered in the future as an adjuvant to the arsenicals in the routine treatment of the average case of syphilis. When conservatively administered, its untoward effects are not greater and of no graver moment than those obtained with mercury.

In cases of jaundice and of arsphenamine dermatitis due to arsenic, in which potent antisyphilitic measures are desired, and in which it is necessary to obviate the reappearance of these untoward states, bismuth may be used with satisfactory results both clinically and serologically. Cases with arsphenamine intolerance as manifested by nitritoid crises, are equally favorably influenced. In addition, in cases in which there is evident a strain of Spirochaeta pallida with its ensuing manifestations, resistant to either arsenic or mercury or to both, bismuth has been of definite potency in controlling all signs and symptoms of the disease.

Although the obtaining of a negative Wassermann should not be considered the solely desired end result in every case of syphilis, it must be admitted that a negative reaction is a source of comfort to both physician and patient, and presents a basis for a more rational and definite plan of future treatment. In obtaining a definite change in the Wassermann reaction in thirty-four per cent. of a total of seventy-nine cases at the end of a single course of bismuth with the probability of a somewhat larger proportion occurring after further treatment, it is easily seen of what distinct value bismuth is in this connection. It has proved far superior to sulpharsphenamine in cases of this nature.

It is suggested that bismuth be given a trial in cases of syphilitic cardiovascular disease when the latter cannot or should not receive arsphenamine or any of its allied products.

It is generally held that the baneful action of irregular and lapsing treatment in syphilis, increases the incidence of visceral and neurosyphilis. A small number of arsphenamine injections administered during a comparatively long period of time, and then followed by the cessation of treatment, places the patient in a state similar to that obtaining in the early incubation period of syphilis when spirochaetes abound and the host exhibits no immunologic response. Ehrlich's explanation of this phenomenon is as follows: "In these patients, the greater number of spirochetes are destroyed by the spirocheticidal action of arsphenamine. So rapidly is this accomplished that the usual tissue immunity which develops as a result of contact between parasite and host is lacking; as a result, a small focus of spirochetes in the tissue of the central nervous system, which may escape the action of salvarsan, develops in the susceptible host with great rapidity and severity." Bismuth, because of its lower spirocheticidal value and slower rate of absorption and elimination, should not when introduced lower the immunological response of the patient to the degree in which arsphenamine tends to. With this explanation at hand, it is thought that the use of bismuth in cases of this character, may be followed by a lower incidence of visceral and neurosyphilis.

From the point of view of expectancy rather than from any proof definitely presented, it is suggested that bismuth be used as an adjunct to the drugs accepted at present as of definite value in the treatment of syphilis of the nervous system.

In the final analysis, it is hoped that the impression is not conveyed that bismuth is a cureall but that it should be resorted to when syphilis cannot be controlled by methods at present in vogue. Its application should be limited to those cases resistant to the arsenicals, or in which it is inadvisable to introduce the latter. In addition its use as an adjunct to the arsphenamines in all types of syphilis in contradistinction to the long established use of mercury in this connection, is presented as a subject to be seriously considered and given further trial.

Bismuth in Syphilis.—F. Green (*Canadian Medical Association Journal,* February, 1925) presents the records of a few cases out of a large series which, he asserts, show that bismuth has in primary syphilis a slow spirocheticidal action as compared with salvarsan, the spirochetes being found in the lesion after the third and fourth injections. In primary and secondary syphilis it has a slower action than arsenic in changing the positivity of the Wassermann reaction, and on account of this slow action it ought not to be used in the abortive treatment of syphilis. In cases of latent syphilis already treated extensivly with arsenic and mercury and are Wassermann fast, bismuth seems to have a great advantage over the other specifics in changing the Wassermann reaction from positive to negative in a short time, although it must be admitted that mercuroarsenobismuth Wassermann fast cases also exist. Bismuth in conjunction with salvarsan seems to be more effective than mercury plus salvarsan in changing the Wassermann reaction from positive to negative, and bismuth seems to be of great help in relieving the pain of tabetics.

Bismuth Salicylate in the Treatment of Syphilis.—S. R. McKelvey, Geo. K. Dunklee, and Nolie Mumey (*Colorado Medicine,* June, 1925) have arrived at the following conclusions: 1. Bismuth is an adjunct in the treatment of syphilis, and is above mercury but below salvarsan in its action. 2. It is better tolerated than mercury. 3. It is less painful than mercury, but causes some discomfort from injection. 4. It is efficient in the socalled Wassermann fast cases. 5. It will clear up primary and secondary manifestations more rapidly than mercury, more slowly than salvarsan. 6. It can be used in patients with marked renal involvement.

Conceptional Syphilis and the Wassermann Reaction.—L. Bory (*Presse médicale,* May 9, 1925) refers to a number of cases of occult syphilis in women, manifested solely in conceptional disturbances, and apparently associated with an unusual mode of inoculation whereby the treponema passes directly into the blood or the peritoneum—both media unfavorable to its development. It is a question in such cases whether infection has actually occurred, and whether the contrast between the perfect health of the mother and obvious syphilis of the fetus is not due to a conservation or culture of the germ coming in from the exterior, e.g., with the semen, in the ovarian or parovarian region, with resulting ability to infect the product of conception, which forms an ideal culture medium for the spirochetes. The frequency of completely negative Wasermann reactions in the blood of the mother while the reaction is positive in the child constitutes an argument in favor of the conception of "germ carriers" which is no harder to accept as applying to syphilis than to tuberculosis, cerebrospinal meningitis, diphtheria or many other disorders.

Medicolegal Notes.

RESPONSIBILITY FOR INFECTION OCCURRING AFTER OPERATION

In an action against a physician for cutting the plaintiff's arm for the purpose of drawing plaintiff's blood for transfusion, contrary to an alleged agreement whereby the plaintiff consented to the operation only upon the condition that the blood would be drawn with a needle and her arm would not be cut, the Georgia Court of Appeals held, Jeter v. Davis, 127 S. E. 898, that the trial court did not err in instructing the jury in effect, with reference to an infection which subsequently developed, that the defendant would not be responsible for anything occurring after the plaintiff left the physician's charge, unless it resulted directly and proximately from the defendant's act; the instructions being warranted by the pleading and the evidence.

STATUTORY EXAMINATION OF PLAINTIFF IN PERSONAL INJURY ACTION HELD NOT TO INCLUDE EXCISION OR X RAYS

Section 19 of the New Jersey Evidence Act provides that in personal injury actions the court may before trial order "an examination of the person injured as to the injury complained of by a competent physician or physicians, surgeon or surgeons, in order to qualify the person or persons making such examination to testify in the said cause as to the nature, extent and probable duration of the injury complained of." The New Jersey Supreme Court holds, Andrus v. Fomfara, 127 Atl. 788, that the statute is not broad enough to give the court power to oblige a plaintiff to submit to an excision of cells from a growth in order to furnish testimony for the defendant as to the nature of the plaintiff's ailment, the plaintiff having alleged that the growth was malignant and cancerous. The court was also of opinion that it should not direct that x ray photographs be taken for the defendant.

TESTIMONY INSUFFICIENT TO SHOW MALPRACTICE

In an action for malpractice in permitting a pad to remain in plaintiff's body after a major abdominal operation, it appeared that the defendant surgeon did not carry the operation through to completion, others, for whose actions he would not be responsible, being involved. The Pennsylvania Supreme Court held, De Rose v. Hirst, 127 Atl. 776, that since the only testimony produced showed that the plaintiff's injuries were caused by an act either of defendant or of some one else not connected with him, the defendant not having undertaken by contract or otherwise to see that the *entire* operation was performed with due care, the plaintiff's case was not proved with that degree of certainty which the law requires to warrant its submission to the jury. Nonsuit was therefore properly entered.

TESTIMONY NECESSARY TO MAKE X RAY PLATES ADMISSIBLE IN EVIDENCE

To justify the admission in evidence of x ray plates, the New Jersey Supreme Court holds, Joy v. Flax, 127 Atl. 596, there must be testimony of the trustworthiness of the process and instruments used to such an extent as to apprise the court that the method used to obtain the plates was one generally recognized as trustworthy. There must also be testimony that the plates depict the condition of the body, or the part of the body, of the person purporting to be the subject of the plates.

The court said: "The general principles governing the admission in evidence of x ray plates are the same as those which govern the admission in evidence of photographs. By the use of x rays a representation of things not discoverable or observable by the use of ordinary eyesight is obtained. Whether or not the x ray plate truly depicts what is not discernible to the eye depends in a large measure upon the correctness of the process and instruments used in making the plates.

CHARITABLE HOSPITAL NOT LIABLE FOR INJURY TO PAY PATIENT BY NEGLIGENCE OF NURSE

The New Jersey Court of Errors and Appeals, D'Amato v. Orange Memorial Hospital, 127 Atl. 340, is of opinion that public policy requires that a charitable institution maintaining a hospital be held not liable for injuries resulting to patients through the negligence or carelessness of its physicians and nurses, even if the injured person were a pay patient; payment for board, medical services and nursing in such case going to the general fund to maintain the charity. The injury in this case was received while a nurse was attempting to remove the patient, who was recovering from an operation, from a wheel chair to bed, the patient falling from the chair. The court was not required in this decision to go so far as to hold that a charitable corporation maintaining a hospital might not be liable to a pationt if carelessness were shown in the selection of the agent responsible for the injury, as that question was not raised in the case.

LICENSING ON LICENSE FROM ANOTHER STATE

The New Jersey Supreme Court holds, Wooding v. MacAlister, 127 Atl., 38, that the state board of medical examiners has discretion as to granting a license to practice in the state without further examination to one proving to its satisfaction that he has been examined and licensed by the board of some other state, so that mandamus will not lie to compel the granting of the license.

ADMISSIBILITY OF DEPOSITIONS OF PHYSICIAN TAKEN IN ANOTHER STATE

The Pennsylvania Supreme Court holds, John v. Reick-McJunkin Dairy Co., 127 Atl., 143, that depositions of a physician who attended the plaintiff in a personal injury case, taken in another state, the physician's testimony including facts given him by the patient, constituting a history of the latter's condition, upon which he based his opinion as to plaintiff's physical ailment and prescribed the treatment to be given, were properly received in evidence.

CHARITABLE HOSPITAL'S DUTY IN SELECTION OF PHYSICIANS

The West Virginia Supreme Court of Appeals holds, Roberts v. Ohio Valley General Hospital, 127 S. E. 318, that it is incumbent on a charitable hospital to use reasonable care in the selection and retention of its physicians, nurses and attendants; and for failure to do so it is liable for injuries received by its patients due to their incompetency.

FINDING OF DEAD BODY SHOWING SIGNS OF STRANGULATION SUFFICIENT TO SHOW CRIMINAL AGENCY

In a homicide case, the defendant being charged with conspiracy to murder her infant child, the evidence showed that the condition of the body of the child, when found, indicated that it had been killed by strangulation. The West Virginia Supreme Court of Appeals held, State v. Toney, 127 S. E., 35, that criminal agency is sufficiently shown where a dead body is found with injuries apparently sufficient to cause death, under circumstances which exclude inference of accident or suicide. In a case of this kind, whether the child was born alive is a question of fact to be determined from the circumstances. Direct evidence is not essential to prove the corpus delicti in any case. It may be proved as any other fact may be proved which is essential to establish the guilt of the accused, namely, by circumstantial evidence.

VOL. CXXII, No. 9 NEW YORK, WEDNESDAY, NOVEMBER 4, 1925 WHOLE No. 2316

The Recognition and Treatment of Neurocirculatory Asthenia in Civil Life*

GEORGE MORRIS PIERSOL, M.D.
Philadelphia

Whenever a large number of persons are taken out of their normal environment and are gathered together under conditions that are unusual and frequently uncongenial, and then are subjected to unaccustomed physical and mental strain, various diseased conditions are apt to develop which would have remained latent and gone unrecognized, in the majority of instances, had these persons been allowed to follow the ordinary course of their lives. It was such conditions as this that brought into undue prominence many functional and organic diseases during the late war, when thousands of young men were mobilized in cantonments, and later on when they participated in actual warfare.

Among the conditions frequently observed among our own troops, as well as in the soldiers of other nations, was the symptom complex variously referred to as irritable heart, effort syndrome, but perhaps more accurately designated neurocirculatory asthenia. This syndrome, it will be recalled, was characterized by symptoms referable to the cardiovascular system, notably tachycardia, palpitation, precordial pain, excessive sweating, cold, mottled hands and feet, and various cutaneous vasomotor phenomena. Of equal prominence were the nervous manifestations such as anxiety, depression, sleeplessness, and marked weakness and excessive fatigability, in some instances associated with vertigo, faintness, dyspnea, and gastrointestinal symptoms. The peculiarity of the syndrome was the insignificant objective evidences of disease as contrasted with the obtrusive subjective manifestations, which soon led to the recognition of the fact that the syndrome was primarily a neurosis in which the asthenia cardiovascular phenomena, which were so outstanding, were the result of functional disturbances of the nervous system rather than evidences of organic visceral disease. The neurocirculatory asthenia syndrome was in no sense peculiar to the late war. It had been recognized by the British in the Crimea, and was accurately described by DaCosta after the Civil War (1). Indeed, his now classical paper furnishes a description of the condition which has not been improved upon by recent writers.

*Read before the American Climatological and Clinical Association at Washington, D. C., May 5, 1925.

Undoubtedly neurocirculatory asthenia still exists, and there can be no question that the condition has always existed among the civilian population. However, until the frequency and clinical features of the condition were emphasized by our recent military experiences, the true nature of the syndrome and its significance were not generally recognized by the medical profession.

During and shortly after the war, medical literature abounded in articles dealing with the various phases of neurocirculatory asthenia. A survey of the literature for the last three years, however, yields scarcely a dozen references to the condition. This suggests that we are as prone to forget some of the medical lessons of the war as we are the economic, the sociological and the military. Because of this and from a desire to reemphasize the importance of neurocirculatory asthenia, as it is encountered in civil practice, this study has been undertaken.

CLASSIFICATION

Neurocirculatory asthenia, or effort syndrome, as it is commonly called by the British, who have also devoted much study to the condition, can hardly be looked upon as a clinical entity, but must be regarded rather as a group of symptoms and signs that may develop under various conditions. This was emphasized by Thomas Lewis, who divides individuals exhibiting this syndrome into six classes. The first, and by far the largest, class comprises those persons who exhibit inherent nervous instability and constitutional weakness. This group includes those who are imperfectly developed or underdeveloped; those whose family histories are bad from a nervous or emotional viewpoint, as well as those who during early life were physically or mentally below par. It was to this group that the majority of the recruits who showed evidences of neurocirculatory asthenia, while still safely in a training camp, belonged. This class also furnishes the greatest number of circulatory asthenics encountered in civil practice.

The second group included those in whom the syndrome develops as the result of fatigue, induced by hard work, lack of rest, insufficient food and exposure. This class furnishes the greatest number of those in whom neurocirculatory asthenia de-

Copyright, 1925, by A. R. Elliott Publishing Company.

veloped at the front. Although exhaustion is undoubtedly a factor in some of the cases encountered in civil practice, it is obviously less frequently the cause than was the case in the army.

In the third group, the symptoms come on after some acute infection such as pneumonia, influenza, acute articular rheumatism, gastroenteritis, tonsillitis, and similar conditions.

The fourth group comprises those persons who are suffering from some unrecognized focus of chronic infection or from incipient pulmonary tuberculosis. Our steadily increasing knowledge of focal infection indicates that in civil life an increasing number of cases come under this head.

Lewis describes a fifth group that was of great importance in the army, namely, those in whom neurocirculatory asthenia developed as the result of gas poisoning. This factor is, of course, negligible as a cause of the condition in civil life.

A sixth and by far the smallest group is made up of persons who are suffering from incipient, but unrecognizable, heart disease.

ETIOLOGICAL FACTORS

Although this classification of Thomas Lewis was made after his study of the condition as it appeared in soldiers, the etiological factors that he emphasizes, with the exception of gas poisoning, are equally applicable to cases that are met with in civilian life. Regardless of all factors that may underlie the condition, the experience of all observers is in accord that there is one fundamental factor common to all cases of neurocirculatory asthenia, namely, nervous and emotional instability which brings about, or is associated with, hyperexcitability or lack of inhibition of the sympathetic nervous system. It seems now generally agreed, that it is this portion of the nervous mechanism that is chiefly at fault and is responsible for the symptoms that are present in neurocirculatory asthenia. This view is substantiated by the work of Cotton, Rapport and Lewis (2). They believe that there exists hyperirritability of the accelerator fibres of the reflex arc. According to Cotton, Slade and Lewis (3), there is also probably present hyperexcitability of the vasomotor mechanism. Neuhof (4) believes that the cardiac and vasomotor symptoms so conspicuous in neurocirculatory asthenia, are due fundamentally to sympathetic hyperexcitation unopposed or insufficiently opposed, by the inhibitory apparatus.

Because the evidences of sympathetic stimulation found in neurocirculatory asthenia resemble in some respects the symptoms of mild hyperthyroidism, a number of observers have looked upon thyroid overactivity as the cause of neurocirculatory asthenia. Harlow Brooks is inclined to this view (5). In a more recent publication (6) he states that he believes that this syndrome stands between exophthalmic goitre and status lymphaticus from a general and symptomatic viewpoint. The weight of evidence, however, seems to refute the statement that the thyroid is a fundamental factor in the production of neurocirculatory asthenia. Addis and Kerr (7) found that there was no relationship between this syndrome and thyroid enlargement. Only four per cent. of the cases of irritable heart studied by Thomas Lewis (8) exhibited probable enlargement of the thyroid gland. Peabody (9) carried out the Goetsch test in a series of sixty-five cases of neurocirculatory asthenia and reported positive reactions in sixty per cent. of this series. Boas (10), however, obtained a positive reaction in only 28.6 per cent. of his cases. Since it is open to question whether the Goetsch test is a reliable index of latent hyperthyroidism, no great significance can be attached to these findings. On the whole, it seems justifiable to conclude that the syndrome, which we designate as neurocirculatory asthenia, is fundamentally a disturbance of the sympathetic system, brought about in those who have congenitally or acquired unstable nervous symptoms, by emotional stress, physical fatigue or infections, either alone or in combination.

The manifestations of neurocirculatory asthenia as it was observed in the army have been described frequently. In order to ascertain whether the manifestations of the syndrome as it is encountered in civil practice differ materially from those met with under military conditions, a series of cases observed in practice during the past few years have been analyzed. As was to be expected, even among the civilian population, this syndrome is overwhelmingly more common in men than in women. In the present series for every eighteen cases that occurred in men, only one case was observed in women. The condition is unquestionably more common in early life. In this series it was never observed after the age of thirty-five. The earliest age at which it was noted was at nineteen. The majority of cases occurred during the third decade.

Neurocirculatory asthenia is observed much more often among those who lead sheltered, sedentary lives and are engaged in the more intellectual occupations, than in those whose labors are largely physical, and who lead active outdoor existences. In view of this it is not surprising that in the series studied, the syndrome was observed almost exclusively in students, clerks, physicians, engineers and lawyers. Only two of those affected led active outdoor lives. One was a railroad brakeman, the other a huckster. Worry, overwork, or overstudy, are noted as the exciting etiological factors in the majority of cases. In twelve and one half per cent. of the series local infections probably played an important rôle.

SYMPTOMS

The most prominent and frequent symptoms of neurocirculatory asthenia are referable to the cardiovascular apparatus. Tachycardia is one of the most consistent findings. This was particularly true as the condition was observed in soldiers, in whom frequently the tachycardia was excessive. As a rule the tachycardia quieted down under rest and during sleep, but it recurred readily with the slightest physical or emotional disturbance. In the civilian cases under consideration a persistent tachycardia of moderate degree was noted in fifty per cent., the pulse rate varying from 100 to 130. The remaining half of the cases showed a pulse rate entirely normal during rest, but a tachycardia of moderate severity supervened upon exertion. Palpitation, the sensation of being conscious of the heart beat, was present in seventy-five per cent. of this group.

Vasomotor phenomena, such as flushes, cold clammy hands and feet, axillary sweating, blue mottling of the skin of the extremities, flushing

alternating with pallor of various skin areas, all recognized as common manifestations of this syndrome, occurred in one half of this series. Precordial pain and discomfort, varying from a mild persistent aching on the left side of the chest, to short acute stabbing pain through the region of the heart, occurred in about one third of the group. The severe, acute anginalike pains, so frequently complained of in the army by those affected with this condition, was not observed in these civilian cases. Faintness, amounting at times to actual syncope, brought on by sudden exertion or emotion, occurred in twenty per cent. of this series. Attacks of dizziness, however, were only noticed in ten per cent.

It would seem, therefore, that practically the same group of vascular symptoms occurred in the civilian cases as was met with in the army. However, it should be noted that the violent palpitation, severe precordial pain and the high rate of tachycardia so frequently complained of by soldiers, did not occur with anything like the same degree of severity in the civilian cases under consideration. A study of these cases leaves one with the impression that as Neuhof (*loc cit*) has already pointed out, the true vasomotor symptoms are more conspicuous in the civil practice than they were in the military.

Dyspnea, particularly marked after slight exertion and under emotional strain, is another well recognized symptom of neurocirculatory asthenia; fifty per cent. of the cases which have been seen in practice presented this symptom. In most cases, the dyspnea entirely disappeared under rest but had a tendency to recur with annoying severity, especially upon any excitement.

As has already been mentioned, individuals suffering from this syndrome are, as a rule, highly emotional and neurotic. In the present series, many of them were highly excitable, exhibiting anxiety over their physical condition and showing a tendency to introspection. Sleeplessness was complained of by twenty-five per cent. In no case, however, did it occur as the distressing insomnia which was so frequently encountered among soldiers. Physical weakness, or perhaps better, extreme fatigability, which was such an outstanding symptom in the military cases, occurs in almost equal frequency among civilians, and it was found in three quarters of this group.

Some cases of neurocirculatory asthenia exhibit gastrointestinal symptoms, which were decidedly prominent. Frequently the tachycardia observed by the patient is ascribed by him to gastric discomfort and distention. Among the civilians studied there were many who complained of a varied assortment of gastrointestinal symptoms including attacks of sudden diarrhea.

In contrast to the subjective symptoms that are so obtrusive in this syndrome, physical examination yields comparatively meagre results. The drawn, anxious, haggard expression, frequently referred to in descriptions of this condition, as seen in soldiers, was not observed in civil practice. The general development of the patients in this series was, on the whole, fairly good. In the majority of cases, however, the thorax had a tendency to be elongated with a poor anteroposterior diameter.

There is unanimity of opinion that in neurocirculatory asthenia, a low blood pressure is the rule. The present group was no exception. The highest blood pressure noted was a systolic blood pressure of 126. In the majority of cases, the systolic blood pressure varied between 100 and 110, the diastolic between 60 and 70.

HEART IN NEUROCIRCULATORY ASTHENIA

In view of the prominent subjective symptoms referred to the heart, physical examination of this region in neurocirculatory asthenia has always been of much interest. In this civilian group there was no instance in which there existed any evidence of enlargement of the heart. It has been generally recognized that it is rare to find an enlarged heart in effort syndrome. Bertnard (11) carried out a series of teleoröntgen estimations of heart size in cases of effort syndrome. He came to the conclusion that in the cases in which symptoms persisted for a long period of time, there was a tendency for the hearts to be smaller than normal. He also found that the long, narrow, dropped heart was not the predominant type found.

Our observation that the heart was not enlarged is in accord with Smith's studies. In twenty per cent. of this series the apex beat was forcible. It resembled in quality the apex beat in mitral stenosis. In no instances was a thrill observed. Systolic apical murmurs that were not transmitted were heard in ten per cent. of the cases. Although the heart sounds were clear in most cases, frequently the first sound at the apex was of a distinctly snapping quality. This snapping sound, heard in some cases of neurocirculatory asthenia, has caused the condition at times to be confused with mitral stenosis. In thirty-three and one third per cent. of this series, arrhythmia, usually of the sinus variety, was noted. In four instances definite extrasystoles occurred. There is, therefore, nothing in the physical signs and symptoms of neurocirculatory asthenia, as seen in civil practice, that in any way distinguishes these cases from those observed in the army. There is, however, a certain quantitative difference, because the asthenia and the cardiovascular and respiratory symptoms also are much less severe and prolonged in the majority of civilians than they were in soldiers.

DIAGNOSIS

The diagnosis of neurocirculatory asthenia at times presents some difficulty. It is likely to be confused with organic heart disease, incipient pulmonary tuberculosis, and mild and atypical hyperthyroidism. The organic cardiac conditions, from which neurocirculatory asthenia must be differentiated, is mitral stenosis. As has already been noted, the tapping quality of the apex beat and the snapping first sound have frequently led to the diagnosis of mitral stenosis. It was because of this confusion that some cardiovascular boards of the army finally demanded that the diagnosis of mitral stenosis be confined to those cases which showed, in addition to the snapping first sound, the well known concomitant physical signs of that valvular lesion. Inasmuch as the classical physical signs of mitral stenosis can usually be elicited by examining a patient's heart in different positions and after varying amounts of exercise, the separation of the two conditions, as a rule, should offer little difficulty.

Added diagnostic difficulty arises in a group of cases not infrequently encountered, especially in civil life, in which to a preexisting but well compensated valvular cardiac lesion the manifestations of neurocirculatory asthenia are added. These latter symptoms have nothing to do with organic cardiac disease and are the result of an entirely independent concomitant disturbance of the patient's sympathetic nervous system. In such cases, when the valvular lesion is allowed to obscure the picture, the treatment directed to the heart alone is consciously inefficient.

In civil practice, at least, there is no question that many cases of neurocirculatory asthenia have been looked upon as early pulmonary tuberculosis. It is obviously perfectly possible for tuberculosis to exist in a patient suffering from effort syndrome, or vice versa. On the other hand, a number of studies have been made that indicate that there is no relationship between the two conditions. King (12) made a careful study of a large group of men with effort syndrome, with reference to the existence in these cases of pulmonary tuberculosis. He concluded that no evidence had been found that there existed more than an accidental relationship between the two conditions. Bond (13) has carefully reviewed a series of five hundred cases in an effort to ascertain the relationship of neurocirculatory asthenia to the development of tuberculosis. Out of these five hundred soldiers who had been discharged in 1919 with a diagnosis of neurocirculatory asthenia, tuberculosis developed subsequently in 3.4 per cent. He concluded from this that in neurocirculatory asthenia the occurrence of tuberculosis was not unduly common. The weakness and the tachycardia which occur in this syndrome are the chief features which might lead to confusion with tuberculosis. On the other hand, the afebrile course of neurocirculatory asthenia, the infrequency of the cough, and the absence of positive physical signs in the chest, serve to avoid this confusion.

The greatest difficulty is probably encountered in differentiating between atypical hyperthyroid cases and neurocirculatory asthenia. There is an undeniable dissimilarity in some of the symptoms, since in both conditions the sympathetic system is at fault. The confusion is rendered greater when a neurocirculatory asthenic has an enlargement of the thyroid gland. The fact, however, that in neurocirculatory asthenia the tachycardia disappears under rest and during sleep, which is not the case in true hyperthyroidism; that if a tremor is present in the former condition, it is a coarse tremor, not the fine tremor noted in thyroid overactivity, taken in conjunction with the increased basal metabolic rate in thyroid disturbances, and the frequent occurrence of some degree of exophthalmus, are helpful points in differentiation.

TREATMENT

The proper management of cases of neurocirculatory asthenia is by no means easy, and is one which is likely to task both the ingenuity and the patience of the physician. The problem involved is economic and sociological as well as medical. The reason that many persons exhibit neurocirculatory asthenia is because they are attempting to lead lives to which they are constitutionally unsuited. This was undoubtedly true in the army, where men developed neurocirculatory asthenia because they were put to work at laborious occupations under abnormal mental stress. These same persons would probably have gone through their entire lives without exhibiting any such symptoms had they been allowed to follow their normal work for which they were both mentally and physically fitted. A similiar situation exists too often in civil life, where untold numbers are constantly breaking down physically and nervously under the strain and fatigue of work for which they are entirely unfit. It is noteworthy that these same persons may and often do, obtain signal success when given an opportunity to work under favorable and congenial conditions.

When confronted with a case of neurocirculatory asthenia, one should first institute a painstaking investigation into the patient's work and habits of life, with a view to readjusting them ultimately, so that the patient may undertake the work for which he is best adapted, both physically and mentally.

In most well marked cases of neurocirculatory asthenia, patients are introspective and exhibit considerable anxiety as to their physical condition, not infrequently being obsessed with the idea that they are suffering from true organic heart disease that will inevitably lead to sudden death. It is essential, therefore, to gain psychological control of these patients and to encourage and reassure them by a tactful, clear and simple explanation of the nature of their illness. It is surprising to see what good results will often follow reassuring a patient that serious organic disease does not exist and that there is no danger of sudden death.

VALUE OF GRADUATED EXERCISES

In the more severe form of neurocirculatory asthenia, a short preliminary period of rest in bed may be of advantage, but in the great majority of cases the inaction and confinement are poorly borne and only lead to further introspection. The methods adopted by both the British and American Army, of giving the neurocirculatory asthenic carefully graduated exercises, is on the whole the most important and satisfactory factor in their treatment. It will be remembered that in all such cases only a very small amount of exercise can be tolerated at first. No exercise should be permitted that produces in the patient undue fatigue, precordial distress, palpitation or tachycardia.

The methods of exercise adopted by the army must of course be modified to meet the altered conditions of civilian life. In most cases of ordinary severity encountered in civil practice, they may begin with some scheme of simple setting up exercises. These can be done at first only in the morning, but later both in the morning and at night. As the patient's strength improves and the pulse rate remains more steady, these exercises may be supplemented by mild outdoor exercise in the form of walks of gradually increasing length, until as further improvement is noted, some more diverting forms of exercise may be substituted, such as golf. Under no circumstances, however, should the exercise be violent or competitive in character or entail undue sudden strain.

MASSAGE AND HYDROTHERAPY

In civil practice, properly given general massage is often valuable in those cases in which the patient is unable to take adequate active exercise. Hydrotherapy in some of its forms may be used to advantage. The simplest form is a tepid or cool bath in the morning, following the setting up exercises. Salt rubs, and the various more elaborate forms of hydrotherapy, may be used with great benefit when they are available and can be properly carried out. All who suffer from neurocirculatory asthenia should cut down their indoor work as much as possible and a maximum amount of fresh air and sunshine should be insisted upon.

MANAGEMENT OF ASSOCIATED CONDITIONS

The various associated conditions must not be neglected. For example, all foci of infection, such as teeth and tonsils, should receive attention. It is of great importance to correct any gastrointestinal conditions that exist. An adequate bowel movement should be secured daily, but there is no advantage in violent or excessive purgation.

DIET

The diet, unless some contraindication exists, should be well balanced and of high caloric value. Although various subjective gastric symptoms may exist, it is a mistake to allow these patients to attempt to live on an inadequate diet.

DRUGS

Drugs may be used in treating various symptoms as they arise, but on the whole they play a subsidiary part in the management of neurocirculatory asthenia. Digitalis has repeatedly proved useless. The condition is primarily a neurosis. It is not in any sense the result of cardiac breakdown, and therefore cardiac stimulants of all kinds should be avoided. In many cases bromides, luminal and other suitable nerve sedatives prove most efficacious. They are particularly useful when the patient is unduly apprehensive or when there is marked insomnia. As the patient improves, even these nerve sedatives may be reduced gradually, and stopped as soon as possible. To overcome the tendency to vasomotor instability, adrenal preparations have been advocated by some in the treatment of neurocirculatory asthenia, with results which are said to be beneficial. It is impossible to lay down any definite, hard and fast rules for the treatment of this or any other neurosis, that would be applicable in all cases. Every case requires careful individual study, and the regimen adopted must be nicely adjusted to the mental and physical needs of each patient.

Prognosis in Cancer*

LOUIS HERLY, M.D.
New York

Cancerous growths, as you know, are malignant tumors which grow out of themselves, that is, by an increase of their own cells. Such an autonomous growth is also observed in many benign tumors which formerly were sharply differentiated from the cancerous growths. Lately, this differentiation has become less sharp, not only because the degree of malignancy may change in the same tumor, but because benign tumors may become malignant. We experience, not rarely, that in what is now an undoubtedly malignant tumor a histological examination, made some years before, indicated a harmless character. At the present time, pathological anatomists refuse to set up definite criteria for benign and malignant neoplasms. Only the clinic, for practical reasons, still holds to the older conceptions and embraces among cancerous growths all neoplasms whenever they show a tendency to infiltrating growth.

In general, one may say that the new growths which are richer in cells are more malignant than those poor in cells; therefore, those rich in connective tissue stroma are the less malignant. This has become especially clear to us since we have observed in our radium and x ray successes that the connective tissue reaction represents a curative process on the part of the organism.

Judging from our clinical observations, we gain the impression that cancer in youthful persons takes a more malignant course than it does in old people.

A cancer, occurring past the seventieth year, frequently shows a diminished rate of growth; often it seems to remain stationary. Such a standstill, however, is not limited to advanced age, for it shows itself at the beginning of the disease. The cause for this behavior must be sought in the fact that the organism possesses protective forces with which it can bring the cancer growth to a standstill, to a regression, and sometimes even to a complete disappearance. There surely exist spontaneous cures of beginning cancers which can be explained only in

*Read before the American Medical Association of Vienna, April 10, 1925.

this way. In more advanced growths, such cures are rarities, but one may occasionally observe an exceptionally slow course in cases which at autopsy are proved to be cancer.

In certain forms of breast cancer we also often see an astonishingly slow growth, occasionally for over ten years, and not exclusively in the aged either. But the opposite of this, namely, a very rapid development, also occurs.

At the time when we make a diagnosis of cancer of an internal organ it is usually in an advanced stage of the disease. The cases we see early give a better prognosis because our therapy can be applied early.

It often seems to us that the rate of growth of cancer is greater in obese than in thin patients. This should not be confused with cancer incidence in the well nourished and the undernourished. For the experience in Germany since the war has shown that the undernourished are easier prey, and cancer incidence in the latter class has tremendously increased in Germany in the last few years; whereas, in the entire world cancer of the uterus before the age of thirty-five is infrequent, at least one case each day is now seen in a large Berlin clinic, such as the Bumm Gynecological Clinic; and whereas, elsewhere cancer of the uterus below the age of thirty is a rarity, at the Bumm Clinic three to four such cases are seen each week.

In the course of the disease the intensity of tumor growth varies, especially when several tumors are present. The rate of growth is influenced by both external and internal factors. One may make the interesting observation in mouse cancer that the transplanted tumors grow feebly, or not at all when the animals are fed certain foods. Excess of calcium in the food decreases, and excess of potassium (1) increases the rate of growth of transplanted cancers in mice. Hypophysis extract accelerates and thyroid retards. And the frequency of breast cancer among butchers' wives and of intestinal cancer among vegetarians gives ground for further speculation along these lines.

In estimating the prognosis of malignant tumors each localization must be considered by itself. The prognosis in cancer of the skin is entirely different from that of cancer of the breast, of the stomach or of the uterus. Allowing for certain exceptions one could make a list ranging from only relative malignancy to the most fulminating types. The degree of malignancy is determined by the biology of the cancer cell itself and this determines its behavior toward the entire organism; or, in other words, the prognosis in cancer is dependent upon the manner in which the protective forces of the organism are functioning.

CANCER OF THE SKIN

Skin cancers are the least malignant, then follow cancer uteri, scirrhus of the breast and stomach, and cancers of the glandular organs, which are the more malignant the less accessible they are, or the more they involve vital parts of the organism.

Among the scirrhous cancers of the breast, more rarely of the stomach, are found some that grow so slowly that it is best to exclude them from any surgical intervention, for the reason that surgery often acts as a stimulus, and a latent growth will become active after surgical treatment. The skin cancer is favorable material for both radiation and operation. Since skin cancer appears almost exclusively at an advanced age it also has the benefit of the better prognosis of growths occurring during senility. The improved prognosis in cancer of the skin is due to its slow growth and slight tendency to metastization. Of course, there are exceptions. When we speak of malignancy we mean the behavior after radiation or after operation.

CANCER OF THE UTERUS

In cancer of the uterus we find that its lesser grade of malignancy is due to the fact that this form of cancer metastasizes rarely, and if at all, late in the disease. Also, as the bleeding is an early symptom, the patient soon consults her physician and so receives the benefit of early treatment. Instruction of the public regarding cancer by physicians, popular lectures, cancer weeks, magazine and newspaper propaganda is bearing good fruit.

In cancer of the uterus we have two methods of radical treatment which have become competitors. These are the advanced method of radium therapy and operation followed by prophylactic raying. The gynecologists, who have the advantage over the surgeons of using both methods, are able to show very creditable results with either form of treatment. A comparison of the results of radium treatment and of operation shows the following: If we set operative cures at an average of twenty per cent., we can safely say that this figure is much too high for the majority of gynecologists. Comparing this figure with the twenty-eight and eight tenths per cent. resulting from radium treatment it results in favor of the latter. Though the difference is not very great, one must remember that the considerable primary operative mortality is absent in radium therapy. Also that among the cases resulting in a twenty-eight and eight tenths per cent. clinical cure not less than ninety-four per cent. were inoperable cases, while the operative statistics deal with only forty to fifty per cent. of advanced cases.

In prophylactic treatment with radium after hysterectomy for uterine cancer, reported by Healy (2), of those treated without crossfire no patients are alive; of those treated with crossfire in 1918 (eight cases), five patients are alive; treated in 1919 (four cases), two patients are alive; treated in 1920 (ten cases), seven patients are alive; a total of sixty-three per cent. of the patients living in 1924.

SARCOMA

In sarcoma, the prognosis, generally speaking, is not so good, for we are dealing with rapid growth processes appearing frequently in the youthful, and manifesting a great tendency to recurrence and metastasis formation in distant organs. Although the results from raying—radium or x ray—are not brilliant in respect to the duration of the cure, it still is justifiable to ray even the primarily operable, since surgery alone holds out no hope at all. In a series of cases observed by Forssell in Stockholm and treated only by radiation, eighty per cent. were primarily inoperable. The diagnosis was confirmed by the microscope in all cases. In this discouraging group, eighteen per cent. of the patients were alive and clinically free from sarcoma after five years. In

a second group, treated by a combination of surgery and radiation, forty per cent. were primarily inoperable. After six years sixty per cent. were free from recurrence. These figures are remarkable for the reason that many of these cases were so extensive locally that an early recurrence after operation should have been expected. Though it is difficult in this group of cases to estimate the rôle played by radiation therapy, still, the relatively long duration of the results speaks for its value. In a third group of cases, all primarily operable, and treated only surgically, there were only two per cent. of the patients living after two years.

Hardly any other growth regresses and disappears so well under radiation therapy as sarcoma; but no growth recurs so rapidly in spite of treatment. And furthermore, there are forms of sarcoma, especially periosteal sarcoma, that are absolutely refractory to any treatment—surgery, radium, x ray vaccines, toxins, arsenic, or anything else that modern scientific medicine has so far attempted.

CANCER OF THE BREAST

One of the most important localizations sought out by this treacherous disease is the breast. There it occurs so frequently that many cancer institutions report that fifty per cent. of all their patients are cases of breast cancer.

The diagnosis is not always easy. Not rarely chronic mastitis is subjected to radical operation, having been wrongly diagnosed as cancer. Tuberculous disease of the breast often simulates cancer, and in several cases of fat necrosis following injury of the breast a radical operation has been performed under the same mistaken diagnosis. These errors in diagnosis occur in the best institutions and in the hands of the most experienced and skilled men. Mobility of the tumor within the breast tissue, long depended upon as a diagnostic sign, does not always exclude the presence of cancer. Frequently all aids to a diagnosis fail. Therefore, all growths in the breast of a woman above thirty-five years of age are to be regarded as suspicious of malignancy. In general, one may say that the length of time that has elapsed since the discovery of a mass in the breast and its rate of growth vitally affect the prognosis. (The possible early existence of metastases, undiscoverable by any means we possess, of course, must be left out of consideration). The scirrhous form is less malignant than the medullary cancer of the breast. Being usually of the scirrhous type, the cancer seen in male breasts gives a relatively more favorable prognosis. Doubtful cases of breast cancer in which operation was performed solely to avoid wrongly considering them benign, often take on a very malignant course postoperatively.

Breast cancer is the best example of the fact that surgical technic, which at present seems to have been developed to its greatest height, does not sufficiently take into consideration the danger of the implantation of cancer cells into the lymph and blood paths within the operative area. If within eight weeks, or even less, after a radical breast operation it is possible to determine the presence of metastases in the axilla, or above and below the clavicle, which had not been there before the operation, then it is not difficult to suspect that they are due to implantation into the lymph paths, occurring during the operation. The same is true of surgery in other localizations of cancer. These implantation metastases following operations for cancer of the breast are often seen in the stitch canals. When, however, the operation was performed on a part located internally, such evidence of implantation does not visibly manifest itself. I feel convinced that this implantation and dissemination of cancer cells during operation is one of the chief reasons for the numerous surgical failures. This was strongly emphasized at a recent French surgical congress. What is true in France in this respect is true also in all other parts of the world; and, therefore, we must look for other means of treatment than purely surgical. Probably the most successful attempt to improve the results is found, at present, in the combination of surgery with physical agents. Visits to the cancer institutes disclose that the mortality statistics of this dread disease have been considerably improved by these measures.

It should be mentioned here that beside implantation metastases, other recurrences following operation are also observed. These latter seem much more difficult to influence than is the primary tumor. This observation has led Wintz in Erlangen to drop operation entirely and to subject all mammary cancers to x ray treatment only. In my opinion this is a hazardous method in the present state of our knowledge, although Wintz speaks of eighty-five per cent. (!) cures over a two year period of observation.

When we consider the multiplicity of the causes of cancer it becomes manifest that to carry out a specific therapy places before us a manifold and difficult problem that always has, and still is, baffling science. For there come into consideration as causes of cancer animal and plant parasites, chemicals, such as anilin and tar, and physical irritants.

Furthermore, chronic inflammations cause a predisposition, that is, changes of metabolism in the tissues, which some day may lead to cancer formation. What the exciting factor is we do not know in most cases. We only know that these changes must exist uninterruptedly over a long period of time, for a cancer formation finally to occur. But we also know that on the basis of these inflammations arise not only malignant but also benign tumors; and also, that what at first may appear benign may later become malignant.

In estimating the prognosis of cancer after operation, it is of the greatest importance to consider the fact that in the majority of cases recurrences and metastases develop within the first year of observation, and of these, at least one half develop within the first six months. In the cases where a deficient operative technic is to be blamed for implantation metastases, they occur the most rapidly, often after four to eight weeks. In general, one can assume that if after two years there is no recurrence it will not take place later and also that the danger of metastasis is less.

The question frequently arises whether the later development of tumors is always a metastasis, or whether it is a second primary tumor which develops in a tissue now predisposed to the disease. Surely not everything that is considered a metastasis is really one. Roesle has shown that in cancer the disposition to tumor formation is widespread—in more

than half the cases there are other tumors beside the carcinoma, though, naturally, the latter dominates the picture. Operation can do away with only the completed tumor formation, but it cannot prevent a new primary tumor formation in predisposed tissue.

The prognosis of cancer is also dependent on the age of the cancer patient. Malignant tumors have their favorite ages. Statistics show that sarcoma appears before the fortieth year, mostly between twenty and thirty; cancers of the digestive tract after the fortieth year and principally between the ages of fifty and sixty. Only the rectal carcinoma is one of senility and if one has no cancer up to the seventieth year, he is as good as safe from cancer with the exception of rectal and skin cancer.

CARCINOMA OF THE RECTUM

The rectal carcinoma when it appears after the seventieth year of life is comparatively benign. It may drag on over years and if a threatening ileus does not make operative intervention imperative it may exist for ten years or longer. The surgeon should, whenever possible, leave such cases in the aged alone. But, if anything at all is done, only an artificial anus should be made to prevent irritation of the tumor by fecal masses passing over it. Radium treatment, when conservatively applied, is far preferable to a dangerous radical operation. The technical errors made by the insufficiently trained, who have discredited radium treatment in these cases, were the effect of a too intensive dose causing burns which tortured the patient more than the carcinoma had done before. One should be satisfied to have the radium diminish the size of the growth, so making the lumen of the intestine larger and diminishing the subjective complaints. At an advanced age, it really is not imperative that everything should be radically removed, since even the tendency to metastasis formation is slight. Everything that has been said about rectum cancer in senility is also true of breast cancer. One should carefully consider whether it is not more advisable to refrain from radical therapeutic measures in cancer occurring in senility.

If radium is applicable in any given case, one cannot consider such treatment a serious intervention. X ray treatment, on the other hand, is not as harmless. In an old person it is not an indifferent matter to have the patient remain for sixty minutes or more in absolute quiet and lying in an awkward position. And the raying for several hours, as it is now practised in some quarters, constitutes a danger to life even in young individuals.

TRAUMA

We now come to the question of the influence of trauma on the development of cancer. Many patients trace the development of the growth to a preceding injury and numerous authorities maintain the same viewpoint. This question is not easily answered. "The relation of malignant disease to injury is frequently raised in medicolegal inquiries. That carcinomatous and sarcomatous tumors develop after an accident close to the site of the injury, and that the one is the direct sequence of the other there is not the least doubt. How the tumor comes we do not always know. A man receives an injury to the right side of his chest and dies ten months afterwards from malignant disease of the liver. Another man falls on his head in a shipyard and a year or two afterwards dies from a sarcomatous growth in the brain." (3)

In the cancer cases occurring in young persons, especially sarcoma, there often seems to be a positive connection between traumatism and the development of the disease. The statistics of one cancer institute show such a connection in thirty per cent. Taking the statistics embracing a large number of institutions this connection between traumatism and the development of sarcoma cannot be definitely established in quite so large a percentage; but it is also impossible to deny it entirely. For there are cases where, at the time of the trauma, neither the finger nor the eye can detect the existence of a tumor. But there is no doubt at all that in cases of already existing carcinoma or sarcoma a traumatic insult exerts a harmful influence. The observation is frequently made that a relatively benign course may, as a result of injury, become a rapidly progressing malignant one and that rapid metastization takes place, as Lubarsch has shown. Knox has called attention to the fact that even the frequent and energetic palpation of breast cancers during routine examinations squeezes the cancer cells into the lymph vessels, as was microscopically demonstrated.

PREDISPOSITION

As far as family predisposition is concerned one must admit that not infrequently one runs across groups of parents, children, uncles and aunts all afflicted with cancer. There is, also, probably such a thing as a hereditary predisposition and then we find the cancer always occurring at about the same decennium of life. A contagion with cancer cannot be seriously considered. *Cancer à deux,* the cancer of husband and wife, is very rare.

Williams (4) observes that "If cancer could be proved to be an inoculable contagious malady, the question as to its causation would be greatly simplified, in favor of extrinsic factors, but, so far as we have hitherto examined this question, no reliable evidence of contagion has been forthcoming." He adds that he never noticed "a single fact that could possibly be construed as evidence of the communicability of malignant disease from one human being to another."

SURGICAL TECHNIC

We have seen that the fate of the cancer patient in whom the tumor is still localized, and who has no demonstrable metastases, depends upon the success of the treatment—operation and raying. That the surgical technic in all large institutions of the world is today skilfully and thoroughly applied cannot be denied. The number of cancer cases where one can establish a faulty surgical technic is comparatively small. Consequently it is the more remarkable to observe that a considerable number of cases a short time after operation, often not more than one or two months, give distinct evidence of lymph node metastases, which we cannot assume were present at the time of the operation and were overlooked. It is, therefore, not unfair to demand that immediately after operation prophylactic aftertreatment with x ray or radium should be undertaken,

RADIATION TECHNIC

Not so much can be said for the technic used in raying as for the surgical technic. In the first place, much confusion exists in this branch of therapy as to apparatus, dose, and other factors. The majority of patients seen by a cancer institute have before their admission been either insufficiently or excessively rayed. Antiquated apparatus not suitable for therapy is used by one; another permits the treatment to be carried out by some lay technician without proper instruction about the individual case. It is to be remembered that the technic of radiation therapy can be learned only by long practical experience just like the technic of surgery. Just as little as one can learn to operate by watching a good surgeon a few times, so one cannot learn radiation therapy in this manner. And, furthermore, it should be emphasized that the radiation technic employed must always be the result of the most careful study of each individual case and that it cannot be carried out according to a scheme tacked to the wall which has been copied from a book or supplied by the manufacturer of the machine. The carcinoma and sarcoma dose propagated by Erlangen is a myth. The mere possession of an x ray apparatus or a certain amount of radium is not sufficient. But one must by serious application become expert in the field before assuming the responsibility of treating those ill with carcinoma. I have heard of instances where cancer patients were treated with Alpine light as a substitute, while the x ray apparatus was in repair. These many digressions from the scientific path have led to discrediting the raying of malignant growths. It is easy to understand that the surgeons rather do operations which they understand than use radiation therapy, which they are only hazily informed about. Both physicians and patients take radiation as a method of treatment much too lightly, for it is not only a difficult method, but a far reaching one. Frequently a mere regression is confused with a cure and the patients withdraw from further treatment, in this way courting disaster, which is sure to overtake them.

MORTALITY

The mortality from cancer is almost as large as that from tuberculosis and after the fiftieth year of life comprises a considerable fraction of the total number of deaths.

Then if radiation is, as I believe, a method to reduce this mortality, it is our duty to see that the cancer patients get the benefit of the best developed technique—surgery and radiation.

Dysentery, Malaria, Intestinal Worms and Other Tropical Diseases*

GEORGE B. LAKE, M.D.
Chicago

The subject of tropical diseases is ordinarily not considered one of keen or pressing interest by the average general practitioner, unless he happens to live along the southern border where many of the diseases ordinarily considered tropical appear with a tolerable degree of frequency. A brief discussion of this class of maladies may not, however, be amiss, as some of them, such as dysentery, malaria and the various intestinal worms, are occasionally encountered in all parts of the country; and the information on the rarer diseases will be given so briefly that it may prove of interest.

AMEBIC DYSENTERY

Amebic or tropical dysentery is very rare in this country, except in the extreme southern states which are practically subtropical in climate. The fact, however, that it *does* occur in the northern states is emphasized by the circumstance that an epidemic has recently occurred in Connecticut, a study of which was published in *The Nation's Health* (1).

The causative organism is the Entameba histolytica which enters the body through the drinking of infected water or the eating of uncooked green vegetables which have been infected either from the water or by being manured with the excrement of human beings suffering from this disease. The pathognomonic point is the finding of the entameba in the stools of the patient. The remedy usually administered is emetine which is given hypodermically in one third grain doses, three times a day, for ten days, with no intermission. Dr. J. G. Smith (2) recommends the administration of the double iodide of bismuth and emetine in daily doses of three grains, by mouth, for twelve days, stating that, under this treatment, the cysts disappear from the stools within forty-eight hours.

BACILLARY DYSENTERY

This form of dysentery is much more common in nontropical regions than the amebic form. The severer cases are caused by the Bacillus of Shiga and the milder ones by those of Flexner or Cruse. Symptomatic treatment should always be carried out in these cases, including absolute rest in bed, with adequate coverings, a diet of albumen water and strained cereal gruels, meat juice and such like. Milk should be avoided and lactose substituted for cane sugar. Jellies and sago pudding may be used.

Buchanan recommends the administration of sixty grains of sodium sulphate every two or three hours until the stools lose their dysenteric character.

*Read before the Medical Round Table of Chicago, April 9, 1925.

SERUM TREATMENT

All authorities agree, however, that the serum treatment offers the greatest probability of a prompt and satisfactory cure. Smith, *loc cit.* states that serum reduces the mortality from thirty-three to fifty per cent., the effect being most marked in severe cases. Dr. A. G. Phear (3) considers it of the greatest value and recommends that it be given early and in sufficient doses (sixty, eighty to one hundred c. c., subcutaneously). The Shiga or Flexner serum should be used according to the type of infection; but, in severe cases, it is dangerous to wait for typing of the organism, which is probably of the Shiga variety, and it is better to give a polyvalent serum immediately, at the same time having the organism typed so that the second dose may consist of the specific serum indicated. In urgent cases, this remedy may be given intravenously, combined with hypertonic salt solution.

Dr. Simon Flexner (4) has published a very favorable report on the use of his serum, recommending doses of from ten c. c. (in children) to twenty c. c. subcutaneously in mild cases; while, in very severe infections, he gives from fifty to one hundred c. c. intravenously. The effects are prompt and the mortality is reduced from seventy to eighty per cent.

MALARIA

This disease, which used to be very common in all parts of the United States, is now comparatively rarely met with except in subtropical regions. In our tropical possessions, such as Panama and the Philippines, all types are present and practically all of the natives have it, either in active or latent forms. Any condition which tends to lower the general body resistance, such as wounds or other diseases or infections, will cause the latent malarial infection to become active, with, sometimes, disastrous results.

TREATMENT AND PROPHYLAXIS

The use of quinine, in doses of five grains daily or fifteen or twenty grains once a week, acts as a very effective prophylactic. This should not be considered a substitute for, but supplementary to the measures to be adopted for mosquito control.

The treatment consists in the oral, intramuscular or intravenous administration of quinine in a *systematic* manner although some cases which fail to respond to quinine are relieved by the use of old fashioned Warburg's tincture. If quinine is to be given by mouth, ten grains should be administered, three times daily, until the temperature has been normal for five days, after which ten grains should be given at bedtime, each night, for eight weeks. The subcutaneous administration of quinine is somewhat dangerous and has no especial advantages. Intramuscularly, quinine and urea hydrochloride should be given in doses of ten grains dissolved in two c. c. of water daily, for one week; weekly for one month; and every two weeks during the second month. This solution is difficult to sterilize and the only way to be sure that it is safe to use is to autoclave it. In some cases the intravenous administration of quinine is most satisfactory. Preparations put up in solution in sterile ampoules are best and seem to act even better when combined with some form of arsenic.

Neosalvarsan has been used intravenously by some observers with excellent results.

HELMINTHOLOGY (WORMS)

In tropical countries, the natives are so universally infested with one or more varieties of intestinal parasites that they would be lonesome without them, and many harbor from two to five varieties simultaneously. Tapeworms are occasionally found in all parts of the country and the treatment with male fern, as it has been practised for many years, is as good as any. The oldfashioned remedy of eating raw pumpkin seeds does well in some cases.

ASCARIDES, OR ROUNDWORMS

Ascarides, or round worms, also are fairly common and, while the use of santonin, as has long been practised, is of value, it is believed that the treatment with oil of chenopodium, as outlined in connection with hookworm, will prove to be more satisfactory in most cases.

This parasite is often considered to be harmless, but it causes great loss of energy and lowering of general resistance in many cases, and may even cause death. There is a specimen in the Army Medical Museum, in Washington, of a human liver in which every large bile duct is packed full of ascarides, which condition resulted in death. A case has been reported (5) in which a mass of forty-nine round worms occluded the bowel and were removed at an operation performed for a supposed intussusception.

HOOKWORM

This is the most serious of any of the intestinal infestations, the parasites involved being the Strongyloides intestinalis (most common in the Orient) and the Necator Americanus which is commonly found in this country. No one will ever be able to estimate the enormous economic losses, to say nothing of the losses of health, vitality and happiness, which have resulted from the depredations of this parasite in our southern states.

The larvæ are present in the droppings of cattle and enter the human host through the skin, usually of the feet, of those who go barefoot over ground fertilized with cattle dung. The initial lesions are called ground itch. The symptoms of a fully developed case of ankylostomiasis are too well known to require restatement.

The treatment formerly used in this disease was to starve the patient for about twenty-four hours and then administer ninety grains of thymol in three equal doses, two hours apart, followed in two hours by a saline purgative. The diagnosis is made by finding the ova in the patient's stools.

At the present time the most commonly accepted treatment is with oil of chenopodium, which is administered, with no preliminary purge or starvation, in two doses of one c. c. each, two hours apart, followed in two hours by a saline purgative. No food must be eaten while this treatment is in progress. Some authorities give the two c. c. of the oil at one dose, preceding it with a purge given the evening before treatment and following it with a saline after two hours. While thymol failed to cure in 23.6 per cent. of a series of cases, this treatment failed in only 7.6 per cent.

Dr. T. M. Lambert, of Suva, Fiji (6), favors the use of carbon tetrachloride (CCl_4) with which drug he has treated over fifty thousand cases among the

natives of the Fiji Islands, with satisfactory results. The adult dose is three to four c. c., given by mouth, although more may be given without danger if the preparation is absolutely pure. Impure preparations are always dangerous. To children he gives two tenths of a c. c. for each year of age from two to fifteen years. He precedes the treatment by a purge of magnesium sulphate the evening before, and gives the drug, covered with water, in a tablespoon. No food, and especially no alcohol, should be taken for several hours before and after the treatment is administered. A purge of magnesium sulphate should be given three hours after the treatment. Dr. Lambert considers carbon tetrachloride a vermifuge and vermicide of great potency for hookworm and oxyuris vermicularis, but not so good as oil of chenopodium for ascarides lumbricoides.

SKIN DISEASES

Skin diseases are varied and prevalent in all tropical countries but particularly the mycoses, or fungus infections, which are most frequently seen in this part of the country as ringworm or barber's itch. The most satisfactory treatment for these cases is to paint the affected parts with a ten per cent. solution of salicylic acid in ninety per cent. alcohol. This may be repeated from one to three times a day as necessary until the parasite is killed. In severe cases involving small areas, the salicylic acid may be dissolved in compound tincture of benzoin, which stays in place better and, therefore, acts longer, but which causes rather severe burning sensations if applied to large and, especially, to sensitive areas of the skin.

PARAGONIMIASIS (LUNG FLUKE)

This disease is rare, even in the tropics, and is almost unknown in this country and of interest only from the fact that it produces symptoms, including hemoptysis, which closely resemble those of pulmonary tuberculosis. The parasite usually enters the body from the eating of infected crabs, passing through the intestines into the abdominal cavity and through the diaphragm into the lung. The treatment is symptomatic, large doses of potassium iodide being the only remedy which approaches a specific.

LEPROSY

Leprosy is quite common in almost all countries where the Malayan or brownskinned race is present. The diagnosis is by the finding of the Bacillus lepræ in the lesions; and the treatment, which is now producing fairly satisfactory results, is by the administration of chaulmoogra oil or its esters. A considerable percentage of cases of leprosy are now being pronounced arrested (as we do with tuberculosis) after this treatment, and returned to their homes.

CHOLERA

This disease has, in years past, been the scourge of all tropical countries, particularly those of Asia, and is now endemic in the Philippines and to a less extent in our other tropical possessions. The etiology is by the ingestion of a cholera vibrio with infected foods or drinks. Death occurs in this disease largely as the result of acute dehydration, the patient frequently losing from fifty to seventy-five pounds in weight within twenty-four hours by the profuse vomiting and purging. If sufficient water can be kept in the system to keep a cholera patient alive for three or four days, he will very generally recover and the treatment, therefore, consists in the intravenous administration of large quantities of warm, physiological salt solution, repeated at frequent intervals, as the necessity of the case demands.

This brief sketch of the conditions which our fellow practitioners in the tropics have to face, and with which I have had several years of experience, will, it is hoped, prove of interest and some of the suggestions relative to conditions quite commonly found in all parts of the United States should be of practical value. For the benefit of any who care to go further into the study of this class of diseases, a brief bibliography is appended.

New Clinical Aspects of the Steinach Operation

HARRY BENJAMIN, M.D.
New York

(*Continued from page* 457)

Case LXIX.—Letter carrier, aged sixty-three. He was first seen in February, 1922. Complained of feeling tired, short of breath when walking fast, urinating frequently at night, but sexually normal. The general examination was negative. The case was considered one of acute exhaustion, due to overwork. He was advised to rest and report back in one year. Patient was seen again in January, 1924, nearly two years later. He had greatly aged. His complaints were more pronounced. He felt distinctly that he could not do his work as he used to. He was sexually much weaker and his memory had become rather poor. His weight was 143 pounds. Blood pressure 140/80. Pulse 72. Skin reaction almost absent. Prostate was larger than two years before. He had lost weight. Incipient senility was the diagnosis. January, 1924, a bilateral operation was done. The patient improved steadily.

January, 1925 (one year after operation), he said he felt as if "new born," while life used to be a hardship before the operation. He was working hard without undue reaction. Sexually perfectly normal. Less nightly urination. Blood pressure 135/85. Pulse 68. Weight 145¾ pounds.

Case LXXVIII.—Physician, aged seventy-one. General decline. Frequent spells of dizziness. Loss of weight. Blood pressure 147/85. Pulse 80. Prostate moderately enlarged. Weight 112½ pounds. The diagnosis was senility. March, 1924, a unilateral operation was done.

No reexamination could be performed but the patient reported in December, 1924 (nine months after operation), that he has markedly improved. Believed he began to improve within a month after the operation by having a more cheerful outlook on life. He says, however, that some of that might have been psychological. Nine months after the operation, his improvement was objective. His weight had increased ten pounds. He had much more physical strength and endurance and he was "able to do things without undue fatigue that were entirely beyond his strength before the operation." He noticed a faster growth of hair and has to see a barber more often; no noticeable change in color of hair. Skin reported less dry. Sexual ability improved. His mental strength and endurance are better. He can "study for a longer period with more satisfactory results." He can concentrate better but has not noticed any change in his memory or ambition. His vertigo is very much improved. He concludes his letter with the following statement, "improved in almost every way to a considerable degree."

Case LXXIX.—Insurance agent, aged seventy. Impotentia for the last year, libido strong, wants to marry again. Feels generally well. Seventeen years ago a gastrectomy was performed on account of cancer (?). Has had no stomach disturbance since. Pulse 60. Blood pressure 160/80. His pulse has an occasional extrasystole. Heart sounds clear. Testes normal. Prostate slightly hard. The diagnosis was incipient senility, impotence. March, 1924, a bilateral operation was done.

No reexamination could be performed, but patient reported in December, 1924 (nine months after operation), a marked improvement all around beginning about two months after operation. Patient had remarried. He described his sexual ability as "as good as at thirty-five years of age." He had much more strength and endurance and an optimistic outlook on life. He wrote, "the operation has been far more beneficial than I could have anticipated. I am in splendid health and am in full possession of my physical powers as I have been at any time in thirty years and sexual intercourse is not accompanied by lassitude but I immediately recuperate. The operation to my mind was eminently satisfactory and all that I could desire."

Case LXXXII.—Mechanic, aged forty-five. Drowsy and tired always. Decided lack of energy for past two years. Losing weight. Frequent coughs. Poor sleep, nervous and irritable. Greatly handicapped in his work. On examination, patient showed moderate diffuse bronchitis. X ray of his chest showed some fibrosis with signs of old tuberculous lesions. Outside of that, examination negative. The diagnosis was premature senility, chronic bronchitis. A unilateral operation was done April, 1924.

No reexamination has been possible but patient reported in December, 1924 (eight and a half months after operation), to be very much improved. He had more appetite and had gained in weight. He noticed that his hair has become heavier. He feels like working. Has lost his headaches and sleeps well. He thinks the operation "has done him a world of good" and "has made a man out of him."

Case LXXXIV.—Lawyer, aged sixty-two. There had been a decline of vitality and endurance for past ten years. Occasional attacks of rheumatism. Sleep was often broken. Erections poor. Had lost some weight. Weight was 121¼ pounds. Pulse 92. Blood pressure 180/105. Occasional extrasystole. Right testis very atrophic. Left, normal. Prostate somewhat enlarged and hardened. A diagnosis of incipient senility with hypertension was made. April, 1924, a bilateral operation was done.

No reexamination could be performed, but the patient reported in December, 1924 (eight months after operation), that he had begun to improve three months after operation, especially as far as his physical and mental strength and endurance and general sense of wellbeing were concerned. He wrote, "I find in work and in play (golf for instance), that I have more energy and power than formerly." His sexual ability had not changed. He also stated that he has neuritis occasionally. In May, 1925 (eleven months after operation), patient reported to be in good health, "in some respects better off than a year ago."

Case LXXXV.—Salesman, aged fifty-five. Lack of pep and ambition, especially pronounced during the last year and a half. Was frequently sleepy during the day, while his sleep at night was disturbed. Had to "whip himself" to his work. Distinct decline in sexual ability. Desire lacking, erections weak and ejaculations somewhat premature. Examination negative. A diagnosis of incipient senility was made. In April, 1924, a unilateral operation was done.

May, 1924 (one month after operation), moderate improvement noticed. More energy, less sleepy in daytime. Somewhat stronger erections. Blood pressure somewhat lower within normal limits.

In December, 1924 (eight months after operation), reported that his improvement had continued and he wrote, "While I have not made the marked changes some others have, I am much pleased and consider it successful to a great degree."

June, 1925 (fourteen months after operation), for the last two months improvement more distinct than at any time before. Working ability perfectly restored. Sleep good and refreshing. Patient was sexually much stronger. According to his statement, the same as between the ages of thirty-five and forty years. Ejaculations, however, were still premature. His physical condition was negative. Blood pressure was somewhat lower within normal limits.

Case LXXXVIII.—Merchant, aged fifty-two. For past thirty years patient had had periodical mental depressions with great general nervousness and inability "to meet anybody." Such attacks occurred once a month and lasted about ten days. Sexual ability had decidedly declined for the last five years, ejaculatio retardata. His mother had suffered from periodical depressions, also one sister. Patient had gonorrhea twelve years ago with right epididymitis. Contracted lues three years later but was thoroughly treated. Wassermann, however, still showed two plus and further treatment was advised. Pulse 68. Blood pressure 160/85. Weight 122 pounds. A

diagnosis of periodical depressions, incipient senility and lues was made. May, 1924, a unilateral operation was done. (Existing lues was considered no contraindication. On account of the old right sided epididymitis, the operation was performed on the left side.)

No reexamination could be performed, but patient reported in December, 1924 (seven months after operation), that he began to improve two months after operation, his periods of depression becoming milder and rarer. He had gained five pounds in weight. His physical and mental strength and endurance, as well as his sexual ability, had improved and his general outlook on life was much better. He feels that the operation will gradually effect a cure. I am inclined to consider the result as positive.

Case XCIV.—Storekeeper, aged forty-four. Patient was a brother of the man suffering from manic depressive insanity described under Case XXIII. He also had attacks of depression several times a year for the last five years, which, however, have become constant and more severe during the last two months. No treatment had been of any help. He had suicidal tendencies. Sexually he had always been below par. Was impotent during state of depression. Patient appeared pale, drawn and haggard. Pulse 76. Blood pressure 100/75. Weight 158½ pounds. Reflexes greatly exaggerated. Skin reaction faintly red, almost absent. Testicles and prostate normal. This was found on first examination in October, 1922.

Patient was examined again in June, 1924 (over one and a half years later). His condition had not changed since and he had, therefore, been in a constant state of depression for nearly two years. A diagnosis of manic depressive insanity was made. June, 1924, a unilateral operation was done (small hydrocele opened at the same time).

In October, 1924 (four months after operation), patient began to feel his depression disappearing. He had more energy and was doing a great deal more business. His head felt clearer. He was sexually stronger. His former constipation had disappeared. Pulse 72. Blood pressure 115-120/70. Weight 166 pounds. Skin reaction distinctly red.

April, 1925 (ten months after operation), patient's face had greatly changed. Drawn expression had disappeared. He looks ruddy and healthy. He has gained nearly twelve pounds. His weight is now 170 pounds. Has had no depression since the operation, although he does not feel equally well at all times. His physical examination is about the same as in October. His formerly exaggerated reflexes, however, are normal.

Case XCVIII.—Music teacher, aged sixty-nine. Had lost elasticity especially during the last year. Occasional attacks of dizziness. Weakness of right hand and right arm especially noticed when playing piano. Felt distinct general and also sexual decline. Wanted to restore his physical and mental strength. His heart was slightly enlarged. Pulse 64. Blood pressure 140/75. Weight 183¾ pounds. Reflexes more distinct in left arm and leg than in right. A diagnosis of incipient senility with myocarditis was made. In October, 1924, a unilateral operation was done.

Patient had sent regular reports, which showed the following: For six weeks after operation he noticed no improvement. Then, however, a noticeable mental quickening took place, with slightly more physical vigor.

In January, 1925 (exactly three months after operation), he wrote that his muscular suppleness had increased and stiffness in his knees had disappeared. His right arm and fingers had become normal and he could use them as well as ever. His mind was more elert and clear. No increase in sexual desire.

In February, 1925 (four and a half months after operation), he wrote, "wrinkles on the back of my hand are smoothing out and my hands are getting plump. My students and friends are frequently telling me that I am looking better than I have in years. I am gaining slowly in physical strength although walking up two flights of stairs still makes me breathe a little rapidly. Sex condition, I think, is slowly improving."

In April, 1925 (six months after operation), patient reported his weight to be 190 pounds. His blood pressure 130/90. He wrote, "my doctor says my heart is slightly larger than normal. My face has filled out quite youthfully. My friends are constantly remarking upon my looking well. Mentally, I am about forty. My physical strength is gradually improving and my sexual strength also. I do not become nearly as short of breath after going up stairs as formerly. Feeling well always."

Case CII.—Manufacturer, aged sixty-one. Gradual loss of strength for several years. Sleep poor. Frequent pain in left leg and in back, diagnosed by his physician as "rheumatism." Sexual ability distinctly declining. Erections fair, but ejaculations premature for the last two years. Examination generally negative. Pulse 88. Blood pressure 132/75. Skin reaction absent. Weight 139¼ pounds. Prostate somewhat large. A diagnosis of incipient senility was made. November, 1924, a bilateral operation was done.

December, 1924 (seven weeks after operation), no change noticed. Pulse 86. Blood pressure 120/80. Skin reaction faintly red. Weight 144 pounds.

June, 1925 (seven and a half months after operation): "rheumatic" pain in leg and back entirely gone. His sleep, as well as general strength and endurance had improved. He had more hair on his chest. Pulse 88. Blood pressure 135/85. Skin reaction distinctly red. Weight 147 pounds. Sexually he had not improved but there is no further decrease in sexual desire and in erections. In spite of the negative sexual stimulation, the general improvement was distinct enough to call the result positive.

Reviewing the results of the cases reported, a great deal of information can be gained.

The principal indication for the operation has been and still remains the process of ageing. Although the decreasing gonadal activity is probably only one of many causes of this process, it still appears to me a most important cause, and I have advised, or consented to the operation only in those cases where a decreasing function of the sex gland activity could be assumed. Such a decrease, however, may begin early in life, due to a congenital inferiority of the gonads and the extreme cases of this group are represented by the eunuchoid type.

A most frequent symptom of this congenital inferiority with hypofunction is sexual impotence,

which, however, constitutes on the whole a small percentage of all cases of impotence. To be quite clear—I am not thinking now of organic impotence (tabes, and other conditions), nor of impotence due to and associated with premature or physiological senility. Each is a chapter in itself. I am thinking of the functional impotence of younger men (juvenile impotence) which forms such a difficult problem in medical practice. In those cases of impotence operation could be performed, if distinct signs of hypogonadism existed, but the operation should be followed up by psychoanalytic treatment, since we cannot imagine a hypogonadal state without corresponding reaction on the psyche. Furthermore, the mental state of the patient may retain inhibitions, fixations, and other conditions, although the somatic foundation of his impotence is removed. The result may thus still remain negative.

Regarding diagnosis of hypogonadism and the indication for the operation, I believe that the physical condition of the testicles is an important factor. I usually test their consistency like an eye is tested for glaucoma. If they are distinctly undersized and flabby, and if a corresponding underdevelopment of secondary sex characters is present, and if these findings are further confirmed by a lack of mental importance of sex life (showing absence of proper erotization of the brain), possibly with other symptoms of an endocrine deficiency, then the operation could be performed—of course, only unilaterally. In other cases of functional impotence, I have occasionally operated, after all other forms of treatment had been exhausted, and where I felt fairly certain that it was not a case of psychic impotence alone. Anyone who would operate too freely in cases of impotence will surely experience great disappointment. The symptom of premature ejaculation, especially, is hardly ever favorably influenced by vasoligation. This is not surprising in view of the fact that this condition is either purely psychic or the result of an inflammatory process of the posterior urethra. In any case we have so far no reason to assume that it is of endocrine origin.

TABLE I

Twenty-one Cases of Hypogonadism and Sex Impotence (Without Signs of Senility or Premature Senility)

Case No.	Profession or Business	Age	Date of Operation	Unil. Bilat.	Time of Observ.
5	Laborer	38	Feb./20/22	u.	
10	Dentist	39	Mar./17/22	u.	2½ Mos.
13	Importer	43	Apr./21/22	u.	5 Mos.
19	Pharmacist	38	Aug./4/22	u.	
20	Dyer	39	Aug./7/22	u.	28 Mos.
21	Patrolman	45	Aug./8/22	u.	28 Mos.
24	Laborer	35	Sept./22 and Dec./1923	u.	30 Mos.
29	Laborer	39	Oct./30/22	u.	
30	Dentist	34	Nov./10/22	u.	8 Mos.
32	Factory-worker	52	Jan./22/23	u.	23 Mos.
36	Secretary	37	Apr./2/23	u.	20 Mos.
45	Clerk	29	Aug./17/23	u.	6 Mos.
51	Salesman	29	Aug./29/23	u.	14 Mos.
71	Engineer	36	Feb./7/24	u.	
87	Salesman	49	Mar./6/24	u.	12 Mos.
90	Ins. agent	37	Mar./13/24	u.	4 Mos.
91	Manufacturer	41	May/14/24	u..	12 Mos.
93	Actor	44	June/6/24	u.	9 Mos.
95	Teacher	27	Sept./11/24	b.	
111	Storeclerk	33	Apr./23/25	u.	
112	Factory worker	33	Apr./27/25	b.	

RESULTS

Strongly positive with constant benefit in two cases (20 and 51).
Doubtful in one case (90).
Negative in eleven cases (10, 13, 21, 24, 30, 32, 36, 45, 91, 93).
No report available in five cases (5, 19, 29, 71, 95).

An assumed congenital inferiority, with early hypofunction of the gonads and functional impotence as the principal symptom and functional impotence unimproved by other treatments, has been the indication in twenty-one cases. In fourteen, a conclusion can be drawn as to the results, which are shown in Table 1.

These results are decidedly disappointing, and it is most probable that the psychic element in those cases was more important than it appeared to be. In only two cases a definite improvement has taken place. In some of the other cases a further psychohygienic treatment may still bring on some results, after the underlying endocrine deficiency has been improved.

To repeat once more, cases of functional impotence which are not due to premature or physiological senility, could form an indication for the operation, if gonadal deficiencies are apparent, but I would advise in all those cases psychotherapy in addition. Patients with the probable diagnosis of a psychic impotence should not be operated on, unless the operation is considered an ultima ratio after thorough psychotherapeutic measures have failed to accomplish results. After such conclusions it appears rather preposterous to still regard the Steinach operation as a "sexual operation." The only sexual element in the procedure is the point where the impetus is given: the sex gland.

Decidedly better results, as far as impotence is concerned, are obtained where the impotence is one of the symptoms of approaching age, either premature or physiological. Here naturally the latter and not the impotence was the indication for the operation.

It is naturally impossible to draw a sharp border line between premature and physiological senility. The age of the patient is no criterion on which the indication for the operation can be based. However, I believe that with very few exceptions men over sixty are entitled to the operation, even if symptoms of a general decline of vitality are not strikingly noticed. The indication would naturally be accentuated, if subjective, as well as objective, symptoms of senility, like beginning arteriosclerosis, hypertension, prostatic hypertrophy, certain forms of arthritis and other conditions can be diagnosed. The principal subjective complaints of these patients were lack of mental and physical vigor, often referred to as pep, decrease of ambition and endurance, tiredness, headaches, poor memory, frequent urination, decreasing interest in sex life and more or less pronounced impotence, weakened eyesight and hearing, etc. Also a study of altered endocrine functions, especially in the sphere of the thyroid or the pituitary, may be suggestive of declining gonadal activity (male climacteric). This group of cases I have classified as incipient senility or simply senility.

I have diagnosed premature senility (with or without any complicating disorders) only where definite signs of decreasing gonadal function existed. Such an acquired hypogonadism will mainly express itself in the form of impotence characterized by an increasing insufficiency of erections, in a moderate prostatic hypertrophy and possibly in beginning shrinkage or flabbiness of testicles. In addition to these symptoms within the gonadal sphere more or less pronounced signs of endocrine deficiencies may exist with symptoms of actual age in men between forty and sixty years of age.

(To be concluded)

Can a Life Be Saved by the Transplanting of an Organ?

Technic of Preliminary Experimental Work

CARLETON DEEDERA, M.D.
New York

From the viewpoint of medical research the most promising cases are those which today are hopeless. The destruction of both kidneys by advanced tuberculosis or by accidental bichloride of mercury poisoning is such a condition.

Many investigators, believing that it would be possible eventually to transplant a living organ and save the life of a dying person, attempted it experimentally. The mistake which has been made is what experiments show,—that transplantations between mixed breeds do not take and always break down in five to ten days at best.

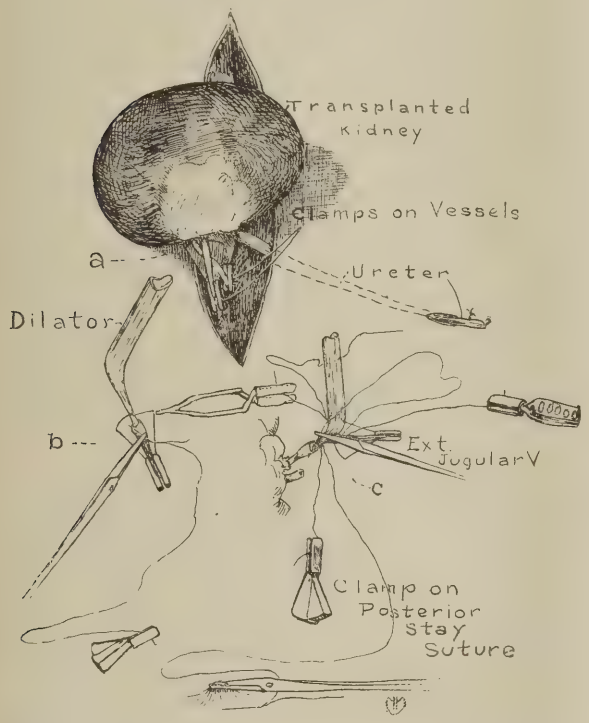

FIG. 1.—At *a* is shown a transplanted kidney with the temporary clamps about to be released and the ureter penetrating the skin and sutured down with one stitch in the lumen. A pocket beneath the deep fascia has been prepared for the reception of the kidney. At *b* is shown the taking of the first stitch in the recipient's vein which is held by a temporary clamp of special design to avoid the possible tangling in the ordinary style. The jaws are rubber covered. The end of the special glass pipette dilates the vein to facilitate the introduction of the stitches. All free ends of suture must be tagged with a clamp, as the raw silk is so fine it is too easily lost. A feature of great aid is to tie a single loop knot holding each thread to its needle. At *c* is shown the completing of the second stay suture over the pipette and uniting further the vein in the recipient with the vein of the kidney being transplanted. All of the stay sutures are inserted in the vessels of the recipient before the kidney is brought to the wound. Care is necessary to keep all of the stitch threads orderly.

After many experiments on dogs of mixed breed, goats and monkeys, a successful transplantation of the kidney with the ovary was accomplished by simply taking two dogs of the same litter. In the human, just how close a relationship is necessary has yet to be determined. Like all of the great advances in surgery it should be tried first on the hopeless case.

The material for renal transplantation is purchasable from the living subject or may be obtained as in mechanical stillbirth, for use of the mother. A newborn baby's kidney is of sufficient size to maintain life in an adult of ordinary size. The mechanical details as based on the following description of technic should be readily mastered.

The simple technic of vascular anastomosis requires only a few fundamental rules to be followed. In transplanting a kidney it is quite unnecessary to attempt to perfuse the organ. It is simply slightly squeezed to rid it of excess blood.

For experimental purposes in the dog the vessels of the neck—carotid and jugular—are admirably suited while in the human the vessels in Hunter's canal are best because later ureteral anastomosis could readily be performed allowing the excretion from the transplanted kidney to enter the bladder.

Both vein and artery should be constantly moist with saline solution. The use of oil in the artery is contraindicated because later it will have to work its way out into the excretions.

A simple way to hold the edges of a flabby vein open while inserting the first few stitches is to use saline in a glass pipette which has had a bulbous tip drawn on it.

FIG. 2.—Shows the completion of all three stay sutures in the vein. A black silk quilt cut something like a pair of pants, covers the wound beneath the artery of the recipient and another such quilt covers the same artery which already has been skinned of adventitia, cut off and had its three stay sutures inserted before covering it with the second quilt. The needle end of one of the stay sutures is about to be used for the over and over stitch around the circumference of the free borders of the veins to unite them. The depth of stitch behind the edge should be at least equal to the distance between each stitch. The distance between stitches should be about two to three times the thickness of the vein wall. In arteries about twice vessel wall thickness is right.

The best suture material is of strands of raw silk. This when threaded on No. 16 needles does the least possible damage to the intima of the vessels.

The adventitia of the recipient's vessels should be stripped peripherally.

Unless the transplanted kidney begins to function within an hour or two it is a failure and should be removed forthwith. When the tip end of the ureter can be made to bleed, it is proof of adequate renal circulation.

The most convenient length for needles is one to one and a half cm. They should have hyper boloidal pointed ends which cause less trauma and leakage than when the points are edged. The needles should be examined with the low power of the microscope to be sure about this. The points can be readily reshaped on an Arkansas stone. If proper needles and sutures are used attempts to get eversion of the intima are unnecessary.

In experimental work the vessels match best if a kidney is transplanted from a larger to a smaller animal's neck.

The ureter from a transplanted kidney should temporarily at least be led through a stab wound and held there with only one stitch passing one half cm. up the lumen.

Although the difficulties of obtaining material for renal transplantation seem of very considerable importance, this is only because the procedure is something new.

552 WEST 113TH STREET.

Skeletal Traction in Fractures*

CHARLES S. JAMES, M.D., F.A.C.S.

Los Angeles

There is an increasing number of fractures occurring as a result of the development of the automobile, the airplane, and other industrial activities. These same causes of the increased number tend to increase the ratio of nonunion cases by producing a change in the character and in the number of the fractures. This is evidenced by more cases of multiple fracture which make a greater demand on callus formation; on account of the more severe trauma to the soft parts, circulation is impaired: and on account of the trauma to bone, osteogenesis is impaired. There is a larger number of compound fractures occurring in which union is always retarded and more likely to fail, therefore the problem of fracture management is becoming more difficult.

The use of the x ray is developing a more exact anatomical requirement, which may result in too frequent manipulation in fruitless efforts to secure a satisfactory reduction, and thus interfere with the natural process of repair. The difficulties so graphically recorded by the radiograph may lead, too frequently, to the open operative reduction thus favoring delayed or nonunion by the mere incision, trauma to the periosteum and soft parts, and even in some cases to the occurrence of infection with its increasing risk of nonunion or even danger to the life of the patient.

The increased number of cases occurring under the operation of the compensation laws and the attendant numerous inspections and examinations by the financially liable insurance companies will serve to educate the public to expect and require more perfect anatomical and functional results. This may also tend to increase the number of malpractice procedures instituted and thus excite on the part of the medical profession, a greater interest in the subject of improving fracture end results.

No fracture is properly handled unless as an end result we secure for the patient the maximum of function and the minimum of deformity possible; always considering the factors present in the individual case.

Our mechanical task is to provide and maintain close apposition and true alignment; to protect the organizing matrix and young callus as it develops; and to allow unrestricted circulation in the adjacent soft parts.

One of the many activities of the American College of Surgeons, for the past two or three years, has been to elevate the plane of fracture results through the agency of district meetings; and the collecting of clinical data referable to fractures and fracture management. It is hoped from this mass of data that ultimately the treatment of fractures will be more nearly standardized; this will result in much benefit. From this activity alone, we may deduct that there is a need for improvement in our fracture results.

METHODS OF TREATMENT

Generally speaking, there are three methods of treatment of fractures of the shafts of long bones:

First, plaster of Paris or other methods of splinting;

Second, traction and suspension.

Third, open operation and internal fixation.

"There is no royal road to success," competent men secure favorable results by any of these methods. It is certainly not our purpose to criticize any method; each possesses its particular advantages and disadvantages. It cannot be held that all fractures of the type under consideration can be best treated by any one method alone. To best serve our patients we should be thoroughly familiar and experienced with each method and if we then individualize our fracture cases and select that method best suited to meet the needs of the individual case, our end results will be improved.

The plaster method offers the advantage of greater movability, often allowing the patient to be up and about on crutches; this favors circulation and has a good mental effect on the patient, thus

*From The Surgical Department of National Soldiers Home Hospital, Sawtelle, California, and delivered before The Santa Monica Branch of the Los Angeles County Medical Society, at Clinic held in the hospital, August 11, 1925.

improving the general physical welfare; it is less time consuming, for when the cast is properly applied and hardened there is little else to be done until the time of its removal.

The disadvantages of the plaster method are: General anesthesia is usually required for reduction and application; if improperly applied, is useless or even detrimental, i. e., too often resulting in malposition, malalignment, or ischemic paralysis. It affords no possibility of effecting any change indicated by the radiograph; and makes necessary the replacing of the entire cast if a minor change is desired. It is not practical in presence of wounds of the soft structures. It favors joint stiffness and tissue atrophy from nonuse.

It is generally agreed that the third method, the open operation should not be undertaken until all conservative methods have failed, or in the presence of such factors as make it evident, at the onset, that such measures will fail.

The second method, traction and suspension, has the disadvantages of, confining the patient to bed until fixation by callus is effected; less finality than that of plaster for the mechanical devices, and adjustments are at the mercy of the doctor, nurse, orderly, or patient; requiring a high degree of mechanical skill and a comprehensive knowledge of traction principles in its application and maintenance; also it is time consuming and requires much in the way of patience, persistence and ingenuity.

ADVANTAGES OF SKELETAL TRACTION

Some of its advantages are: Usually no general anesthesia is required; the patient is more comfortable; a greater freedom of movement and attention to personal needs is allowed; it permits frequent inspection and mensuration of the affected limb; more frequent x ray records of progress; easy correction of minor defects in apposition or alignment; earlier movement of joints; and permits massage and physiotherapy, thus lessening the final disability due to nonuse.

Skeletal traction when applicable affords the most ideal method of effecting extension.

Referable to its advantages, permit me to quote from a former article (1) on fractures, as follows:

"In nearly every fracture case, four major elements must be considered vis: approximation, alignment, function and pathology of soft parts.

"In the event of failure to any degree of the older methods of treatment, attention is naturally directed to some of the newer methods in effort to avoid open operative treatment with its attendant special risks and responsibilities. It is here that suspension and skeletal traction will be found to afford a far wider application than it has enjoyed in the past.

"It should be remembered that 'the inherent value of any apparatus is of less importance than the skill with which it is used,' hence, then, we may be able to turn evident defeat in many cases into victory by the skillful use of the Balkan frame, Thomas splint, suspension and skeletal traction with the Steinmann pin or modified tong device, without an open operation.

"These methods of extension seem barbaric to one who has not used them but in practice they are much more comfortable to the patient than any other method in which a considerable amount of weight has to be continually applied as the traction is directly on the non-sensitive bone instead of the sensitive skin.

Steinmann (2) pointed out the objections to skeletal traction and their avoidance as follows:

"First: Pain—If the skin is pulled up forcibly when the pin is inserted there will be no skin pain or decubitus.

"Second: Infection.—The skin should receive careful attention and preparation to avoid sepsis. The pin should not be introduced in a hematoma about the fracture, in the marrow cavity of the bone or a joint cavity, nor in the epiphyseal line."

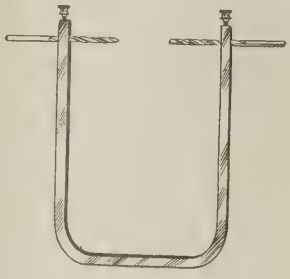

FIG. 1.—Skeletal tractor (James).

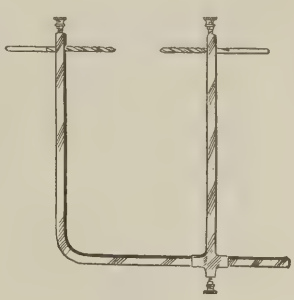

FIG. 2.—Skeletal tractor, adjustable (James).

Skeletal traction is a safe procedure if proper technic is employed, because its limited site of attachment is of great value in the presence of extensive abrasions, or compound fractures with much destruction of the soft parts; also in multiple fractures especially where proper alignment is difficult to secure. Extension at the beginning of treatment should provide an overpull to lessen the fixation of injured muscles in a shortened condition.

Suspension and traction afford early and frequent mobility to the adjacent joints. The benefits of passive motion can be secured from the beginning of the treatment. The apparatus lends itself to easy manipulation in providing the desired position and extension. It allows the patient to vary the elevation of the limb to suit convenience and comfort, and affords the maximum amount of freedom in bed. It gives greater facilities for checking the progress results by radiographs and there is less interference with circulation, less edema, annoyance, pain and discomfort. It permits increased facilities for personal cleanliness, therefore the nursing care of the patient is rendered much easier.

Blake (3) stated, "Skeletal traction is the most perfect method by which traction can be made upon the femur because it permits the placing of the limb in an absolutely correct position, and acts directly upon the fragments without fixing or injuring the knee. With it, a weight of six kilos produces as much effect as fifteen kilos attached by ordinary adhesive bands. The objection to it is the fear of infection at the site of the pin or tongs, but present experience seems to prove that the tongs at least may be employed with impunity."

Skeletal traction by pulling upon the bone direct is far more efficient than is plaster skin traction and

its application is not restricted by blebs, abrasions, contused skin and open wounds. It can be applied immediately with maximum traction force, in order to secure reduction of the fragments at a most opportune time, before muscle infiltration, rigidity, and retraction occur. These advantages cannot be so easily secured by adhesive plaster because of slippage.

Skeletal traction should be removed as soon as the fragments are firmly held by callus and may be supplanted by plaster or splint until final union is secured.

In the application of skeletal traction many devices have been offered, from the transfixing pin as advised by Cordavilla (1903) and by Steinmann (1907), to the complicated types of tongs, clamps, and other devices, many of which are good and all possess points in their favor.

After considerable experience with the various types of skeletal tractors, I have devised a simple instrument which has proved entirely satisfactory and effective. In the accompanying photograph (Fig. 1) it will be noted that this skeletal tractor is a three eighths inch square steel bar, shaped to a clevis or U shape, carrying at each open end a No. 20 drill bit, at exactly right angles and securely fastened in position by milled head setscrews, thus rendering the entire apparatus rigid. Fig. 2 shows the same instrument with an adjustable feature, making but one instrument necessary for the various sized limbs, otherwise the principle is the same as Fig. 1.

This skeletal tractor offers the advantage of simplicity in its construction and application.

TECHNIC OF APPLICATION

The skin area is iodinized; the local area is anesthetized by novocaine solution, extending in depth to the bone; the skin is held taut opposite to the line of traction; with a small tenetome, a one fourth inch incision is carried directly down to the bone and a No. 20 drill bit is inserted through the tractor arm and set in the bone to the desired depth; likewise another drill is inserted on the opposite side; the two drills are fixed in rigid position by the set screws; then a gauze dressing is placed around each drill for wound protection and the procedure is complete.

The grooving on the sides of the drill acts as a drain from the bone. The drills being rigidly fixed at right angles, afford security against slippage or undue penetration.

Ample strength is afforded for traction applied by small sash cord secured in the center of the base of the U by adhesive plaster. This right angle fixation permits rotation of the skeletal traction, on its fixation point in the bone, and if a lateral change in traction angle is desired the sash cord may be fixed to either side of the center of the base of the U, or if desired, other lines of supplementary traction may be easily secured.

Some Observations on Eastern Clinics*

JAMES A. MATTISON, M.D., F.A.C.S.

Sawtelle, Calif.

It was my pleasure to spend some time in several of the Eastern and Midwestern hospitals recently.

CLINIC OF DR. JOHN B. DEAVER

When in the East, I never miss an opportunity to visit the clinic of Dr. John B. Deaver. Notwithstanding the fact that Dr. Deaver is around seventy years old, he is still doing more work than any man I have ever seen in action. Dr. Deaver is surrounded by a group of extremely capable young men, and every case in his clinical material is thoroughly worked up before coming to operation.

If one has not been in this clinic for two or three years he will notice that Dr. Deaver is doing more radical work in dealing with ulcers of the stomach than formerly, especially in dealing with crater ulcers, and he is doing more conservative work in dealing with ulcers of the duodenum, and focal infections in the cecum and colon. Dr. Deaver, as well as other surgeons who have had a wide experience in work along the lines of that advocated by Mr. Lane of England in cases of focal infection in the sigmoid and colon, admit that their results from the radical procedures have been disappointing in many cases, and much of this work has been abandoned.

The first case presented for operation in Dr. Deaver's clinic was a case of intestinal obstruction. The case was of special interest to me in view of the fact that the patient had been operated upon three weeks previously for a "carcinoma of the duodenum." A resection of the pyloric end of the stomach and as much of the duodenum as possible had been done at that time, also a posterior gastroenterostomy. This case was particularly interesting because of the fact that clinical experience has demonstrated that malignancy of the duodenum is extremely rare.

The findings of the second operation revealed considerable leakage of bile, greatly distended intestines, and a band of adhesions across one loop of the small intestine, the latter being the immediate cause of the obstruction. In commenting on this case Dr. Deaver emphasized the fact that he had "saved many lives by promptly reopening the abdomen follow laparotomies, where definite symptoms of obstruction followed within a few days or a few weeks." In connection with the causes of intestinal obstruction and

*Read before the Santa Monica Branch of the Los Angeles County Medical Society Clinic, held at the Soldiers' Home Hospital, August 11, 1925.

acute abdominal conditions, Dr. Deaver gave an analytical clinical talk on this subject. He gave acute abdominal conditions the following order of frequency in his experience:

Acute appendicitis
Perforated peptic ulcer
Acute salpingitis
Acute intestinal obstruction
Ruptured extrauterine pregnancy
Acute pancreatitis
Acute hematogenous infection of the kidney
Twisting of the pedicle of an ovarian cyst
Acute diverticulitis
Mesenteric thrombosis, and other conditions.

The points which Dr. Deaver emphasized most strongly in making a differential diagnosis was, first, a thorough clinical study based on a careful case history; and second, a careful anatomical study of the case. In this connection he emphasized the fact that such a study will, in the majority of cases, lead to a proper diagnosis, and will, therefore, result in early operative treatment, and avoid many disastrous results, traceable to delays in administering the proper treatment.

He emphasized the fact that a higher mortality of "the acute abdomen" is due in part to a lack of an intimate knowledge of living surgical pathology, and in part to too great a reliance on laboratory findings which do not always correspond to the operative findings; and in the third place, too long a delay in adopting the proper operative treatment instead of pursuing the socalled conservative method.

In connection with his work in jaundice cases Dr. Deaver emphasized strongly the great importance of a careful study of all organs from both a physiological and pathological viewpoint before operation, and insisted that this examination should include especially the determination of heart, kidney, and liver functions, the blood pressure, coagulation time, chemistry, Wassermann test and other findings. In his preliminary treatment in these cases of jaundice, of whatever nature, he insists not only on the administration of calcium lactate intravenously, but glucose and in some cases insulin, with or without glucose, for three or four days before operation. In this connection, the importance of watching for acidosis following operation, and the proper followup treatment, was also emphasized.

CLINIC OF DR. GEORGE W. CRILE

The next clinic visited was that of Dr. George W. Crile. Dr. Crile's clinic, like that of Dr. Deaver's, is always a source of great inspiration, as well as of information.

His method of dealing with cases of goitre is unique, and his technic is typical of the man. With the exophthalmic goitre cases Dr. Crile is one of the men who recognized clearly the importance not only of dealing with these patients from the viewpoint of physiology and pathology, but recognized the importance of dealing with them from a psychological viewpoint. His goitre patients are given the necessary amount of rest treatment in bed, and in those in whom he feels that it is indicated, he even has gas administrated in small quantities one or more mornings before the actual date set for operation, in order to get his patient accustomed to the ordeal. This, of course, is done only in cases where gas anesthesia is administered.

Much of Crile's goitre work is now done under local anesthesia. Since the introduction of the iodine treatment in the form of Lugol's solution prior to operation, pole ligations are seldom indicated in his clinic. The anesthesia most used in this clinic is novocaine, or a combination of novocaine and nitrous oxide and oxygen. Ether is comparatively infrequently used in this clinic, and ethylene, never. All goitre patients are operated on in their own bed in their private rooms, instead of being taken to the operating room.

In connection with his talk on goitre operations, Dr. Crile referred to the fact that recently an Austrian anatomist had worked out the minute anatomy of the various branches of the recurrent laryngeal nerve crossing the trachea. For a number of years Dr. Crile has recognized this fact emphatically, and has strongly advocated leaving some thyroid tissue on the front of the trachea and not denuding it entirely of thyroid tissue, for the reason that he asserted such procedure would result in greater discomfort to the patient by a greater intratracheal accumulation of mucous.

In connection with the work on gastrointestinal surgery, Dr. Crile emphasized the fact that his views do not coincide with those of many surgeons in Europe on the treatment of gastric and duodenal ulcers, especially in the stand which is being taken very extensively on the Continent in carrying out extremely radical measures in treating both gastric and duodenal ulcers. Dr. Crile emphasizes strongly that his experience with the conservative treatment of chronic crater ulcers in the lesser curvature of the stomach has been disappointing. He states that his experience has been that a crater ulcer of the lesser curvature of the stomach calls for a radical operation; that is, a partial gastrectomy, followed by a gastroenterostomy. He does not, however, recommend such radical procedure in the case of simple ulcers.

In dealing with carcinoma of the sigmoid and rectum, Dr. Crile stated that many inoperable cases had come to his clinic, all of which he had referred to the radiological section for x ray and radium treatment. He stated that the results had been so good, in some cases, that he had been referring more and more of the borderline cases for the radiation treatment, and that the results had been far better than he had originally anticipated. (In this connection, he stated that his results from x ray and radium treatment had been so favorable that in case he should develop a carcinoma of the rectum himself, he should consider very seriously the use of this form of therapy instead of surgery.)

DR. OCHSNER'S CLINIC

Dr. Oschner's Clinic. Each time I have had an opportunity of visiting Dr. Oschner's clinic (and that has been once a year for a number of years), I have been more and more impressed with the originality of this operator, and the many evidences of his conscientious work. Dr. Oschner, as in the case of the other men referred to, has always been insistent upon each case being carefully worked up and properly prepared before the patient is brought to operation, and after the patient comes to operation, his practice has always been to eliminate all pathological conditions, if possible, at the time of operation.

One of the patients operated upon in his clinic during my visit was a splendid illustration of this

fact. The patient had a celiotomy. An ulcer of the duodenum was found and a posterior gastroenterostomy was done. The gallbladder was examined and found to be pathological. A cholecystectomy was done. The appendix was examined and found to be thickened and adherent. An appendectomy was done. It was noted that a much greater engorgement of the veins of the stomach and transverse colon was present than he had been able to explain. The liver was examined and found to be more or less enlarged. This still did not explain satisfactorily the venous engorgement, and the spleen was explorated and found to be about three times normal size. He stated that this was a case of beginning of Banti's disease, and at the same operation did a splenectomy. Space will not permit of further clinical observations.

Since this, Dr. Oschner has died, as you all know. We, among his numerous admirers, miss him greatly.

THE MAYO CLINIC

In addition to the great volume of clinical work which is being carried on in the Mayo clinic, the thing that we naturally are always greatly interested in is the extensive research work which is being carried on in every department of this clinic. This is indeed an outstanding feature of the clinic. To the research department of this clinic is due the credit for some great advances in medical science during the last few years. One of the outstanding advances which has resulted from the research work done on the secretions of the thyroid gland has been the discovery of thyroxin by Plummer and Kendall. The work of Mann and his coworkers, on the liver functions, has also been recognized as of great importance and as a definite step in advance.

The staff of the Mayo clinic is very unique in the fact that there is such great unanimity in the cooperation of departments; in fact, it can be looked upon as one great unit, and the influence which has made this possible is one of the great factors in making this one of the greatest clinics in existence.

At the Mayo clinic one is always greatly impressed with the enormous number of goitre cases presenting themselves for treatment, and in this connection we are also impressed with the progress which has been brought about from year to year in the treatment, especially of exophthalmic goitre cases: and the research department of the Mayo clinic is entitled to its share of credit for this advance which has been made. No longer than three years ago one observed many cases of far advanced exophthalmic goitre, whose conditions were so critical that nothing more than a pole ligation was possible. The work of Plummer, Kendall and others has materially modified this procedure. At the present time, by the prolonged rest treatment and the use of Lugol's solution, pole ligations have been practically eliminated.

The surgical staff at this clinic are not in accord with the radical procedures which have been carried out in the European clinics of late years in dealing with gastric and duodenal ulcers. This is particularly true in dealing with simple ulcers of the stomach and duodenum—more especially of duodenal ulcers. Dr. William J. Mayo and other members of his staff emphasize the fact that, "eighty-five per cent. of simple uncomplicated gastric ulcers are cured by excision and gastroenterostomy, and that ninety-four per cent. of cases of duodenal ulcer are cured by gastroenterostomy and excision when indicated." They insist that "a radical resection of two thirds of the stomach in uncomplicated cases, as is now being done by many surgeons in Europe, is not justified." They do, however, recommend, and are doing partial gastrectomy followed by gastroenterostomy in cases of large crater ulcers, especially in the lesser curvature of the stomach. Dr. Charles H. Mayo, Dr. Balfour, and Dr. Judd call attention to the fact that "there is a recurrence of gastric ulcer following gastroenterostomy in about two per cent. of cases," but they insist that such a recurrence in two cases out of one hundred does not justify the additional risk of sacrificing two thirds of the stomach as a routine, where nothing more than a simple ulcer exists.

The procedure followed in the Mayo clinic in the case of pathological gallbladders is not different from that followed in other clinics. All diseased gallbladders are removed, unless there is a definite contraindication for the same at the time of operation.

The intravenous injection of salts for visualization of gallbladder has been given up at this clinic, because of the severe reactions following its use. It is asserted, however, that the administration of the salts by mouth is giving practically as good results as the intravenous administration formerly gave. Attention is called to the fact that the visualization of the gallbladder does not show the actual pathological condition present.

Narcosis by Ethylidene Chloride, Methylene Chloride and Their Mixtures

D. M. ROSSIYSKY, M. D.
Moscow, Russia

The power of anesthetics, as a result of their complicated physicochemical molecular combinations with the substances of the protoplasm, essentially depends not only upon the physical and chemical properties of different anesthetics and their mixtures, but also, to a great extent, upon their composition and their combinations with substances acting similarly upon the animal body.

The depth and duration of narcosis are also greatly influenced by the boiling point of an anesthetic or mixture of several anesthetics. The lower the boiling point, as compared to the temperature of the body, the more rapid its evaporation, and the easier its absorbability by the body, the prompter its exhalation by the lungs and, according to Schleich's opinion, the more unfavorable its influence on the respiratory

organs. On the other hand, substances having a high boiling point are not so easily absorbed, remaining in the body for a longer time, and therefore may in the course of continued narcosis cause a deleterious amount of such substances to collect in the body.

If the boiling point of a substance coincides with the temperature of the body, it must be freely exhaled during the act of respiration; substances, evaporating at a temperature lower than that of the body, get into the lungs in a state of intense steam; with substances having a high boiling point, a quantity of it, corresponding to the coefficient of evaporation, will be given off by the body through the lungs at each exhalation.

Consequently, substances with a lower boiling point will produce more rapid, though less protracted narcosis; substances with a higher boiling point will act more powerfully, and with greater duration, but the anesthesia caused by them will set in more slowly.

Thus, depth of narcosis depends on the rapidity with which the anesthetic is eliminated from the body.

A substance with a high boiling point, as, for instance, chloroform, is not entirely expelled by exhalation—a part of it remains in the body, increasing in quantity and power on repeated exhalation. It is difficult for the body to get rid of it, owing to the slow evaporation of the substance, a consequence of which is the danger of overdosing, due to its collecting in the body—a state of things not observed when administering substances with low boiling point. These latter, on the contrary, when in a state of overheated fumes, and, consequently, under increased pressure, are rapidly and violently exhaled by the lungs, causing harm to the tissues during the process. But if narcotic substances are used, the boiling point of which is considerably lower than the temperature of the body (ethyl chloride, with boiling point 12.5° C.) a very brief sleep is obtained which cannot be made deeper even by increased dosing.

REQUIREMENTS OF AN ANESTHETIC

The principal requirements of an anesthetic are the following: 1. To suppress entirely conscious sensibility; 2, to have no deleterious action on the blood circulation and respiration, and 3, to be rapidly expelled from the body.

One of the principal conditions is, on the one hand, the absence in an anesthetic of the chlorine, bromide, iodine group, or their presence in quantities not sufficient to provoke the failure of efficiency of the heart or respiration; and, on the other hand, a higher boiling point than that of ether and a lower one than of chloroform, and best of all, as experimental observations show, a boiling point between 45° and 55° C.

In studying several less known anesthetics of the fatty series, and guided by the considerations mentioned above, I have chosen a combination of two substances, each of which contains a lesser quantity of chlorine than does chloroform, acting on the blood circulation and on respiration less oppressively than does chloroform, and having a boiling point higher than that of ether, but lower than that of chloroform—ethylidene chloride and methylene chloride. Ethylidene chloride and methylene chloride are colorless liquids smelling of chloroform. Ethylidene chloride (CH_3—$CHCl_2$) was first discovered by Regnault and analyzed by Wurtz, 1857, Genter, 1858, and Beilstein, 1859. It was used as an anesthetic in 1870, being proposed by Liebreich.

Chloridene, ethylidene chloride is produced by the treatment of ethan or ethan monochloride with chlorine (Regnault). It is also to be obtained by the treatment of acetaldehyde with chloride of phosphorus, Beilstein, of phosgen with acetaldehyde, of acethylenate copper with condensed hydrochloric acid, Sabaneieff, and as a byproduct in obtaining of choral.

Ethylidene chloride is a liquid insoluble in spirits of wine, ether, chloroform or oils; its specific gravity being 1.204; it has a lower boiling point than that of chloroform, viz.: 58° to 60° C.

Ethylidene chloride contains per 100 parts: C: 24.24; T: 4.04; Cl: 71.72, while chloroform: Cl: 10.04; H: 0.84; Cl: 89.12.

Ethylidene chloride while not inferior to chloroform in rapidity of action, acts more gently on the circulation of the blood than chloroform, while exceeding the latter in rapidity of awakening.

Methylene chloride (CH_2Cl_2); specific gravity, 1.346, was obtained in 1840 by Regnault, analyzed in 1867 by Richardson. Methylene chloride is obtained by the treatment of methane, ethane, monochloride, methyl, methylene, iodide with chlorine, and by treating an alcoholic solution of chloroform with surplus of powdered zinc with an addition of a small quantity of ammonia, Perkin. The boiling point of methylene chloride is 41.5° C. It contains per hundred parts: C: 14.12; H: 2.35; Cl: 83.53.

EXPERIMENTAL WORK

Experiments for establishing the effects upon animals of chloroform, ethylidene chloride, methylene chloride and their mixtures, in which ethylidene chloride and methylene chloride were taken in different proportions, have been carried on by me at the Pharmacological Institute of the Moscow University.

Mixture No. 1. Ethylidene chloride 1 part + methylene chloride 1 part. Specific gravity = 1.228, boiling point 50.5° C. There are 77.62 parts of chlorine to 100 parts of the mixture.

Mixture No. 2. Ethylidene chloride two parts + methylene chloride one part, specific gravity = 1.210; boiling point 52° C.

There are 74.90 parts of chlorine per 100 parts.

Mixture No. 3. Ethylidene chloride one part + methylene chloride two parts, specific gravity = 1.239; boiling point 47° C.

There are 78.80 parts of chlorine per 100 parts.

The experiments were made on dogs, the animals being previously weighed. Experiments were carried on as follows:

After prelminary tracheotomy the animals were given to inhale a narcotic liquid out of a flask, a capacity of about 200 grains, with a wide mouth into which were inserted two bent glass tubes; one of them was attached to the animal's trachea, and the other, lowered almost to the level of the anesthetic, communicated by its other end with the air. In this way the animals inhaled the narcotic directly into the trachea; to determine the pressure of the blood the carotis sinistra or femoralis sinistra were attached to a manometer; the breathing movements and blood pressure were registered in seconds on the smoked tape of a kymograph. Experiments were first made with chloroform, ethylidene chloride and

methylene chloride and afterwards with ethylidene chloride methylene chloride mixtures.

The experiments with chloroform once more showed how painfully animals bear chloroform's narcosis. The first drops of chloroform evoke a state of violent agitation: we have deep, abrupt sighs, jerky movements, spasmodic contractions; the excitement begins to abate some minutes later, the reflexes diminishing, the blood pressure failing to 31.6 per cent to 68.1 per cent, and a state of complete narcosis finally setting in. Later the dose of chloroform being increased the blood pressure falls considerably, irregularity of the cardiac rhythm, stertorous breathing setting in and finally a complete cessation of breathing movements.

Experiments with methylene chloride and ethylidene chloride have shown that dogs bear them better than chloroform, and although the period of excitement caused by the drugs mentioned is not shorter than that of chloroform, the blood pressure and respiration, especially with ethylidene chloride, are not noticeably slackened during narcosis. But on administration of even inconsiderable doses of chloroform, the respiration and blood pressure begin to relax and on an increased dose of chloroform being administered to a dog a cessation of breathing movements takes place and death ensues rapidly, with an abrupt lowering of the blood pressure. In the experiments with chloroform the blood pressure during the cessation of reflexes fell an average of 31.6 to 68.7, while with methylene chloride the blood pressure during cessation of reflexes fell to 17.5 to 28.5 per cent., and with ethylidene chloride to 27 to 29.3 per cent. With chloroform the blood pressure fell to 68.8 to 76.3 per cent. by the end of narcosis, the breathing grew slower and finally ceased, while with methylene chloride and ethylidene chloride, in spite of the administration of a considerable quantity of the narcotic, the breathing did not grow slower till the end of the experiment; with methylene chloride the blood pressure towards the end of experiment fell on an average to 52.2 to 58.7 per cent., and with ethylidene chloride only to 31.7 to 37.7 per cent.

Experiments with mixtures 1 and 2 having proximate boiling points, mixture No. 4 boiling point, 50.5°, and mixture No. 2 boiling point, 52° have shown their favorable action on the blood circulation and respiration, as compared to the action of chloroform, methylene chloride and ethylidene chloride respectively.

The period of excitement caused by these mixtures is inconsiderable as compared to chloroform, pure ethylidene chloride and methylene chloride. On inhalation of these mixtures the reflexes soon begin to abate, a weakening of muscular tone sets in, and complete narcosis ensues, now kept up by inconsiderable doses of the drug; after ceasing to inhale mixtures No. 1 and 2 the reflexes return and awakening sets in quite soon (in two to four minutes) without being followed by any undesirable aftereffects. With chloroform the blood pressure falls noticeably on comparatively small doses being administered; breathing is slackened and death finally sets in from paralysis of the respiratory centres. With narcosis by ethylidene chloride and methylene chloride mixtures the blood pressure and respiration did not noticeably slacken during the whole narcosis period which lasted longer than with chloroform, although a larger quantity of the narcosis was administered. Narcosis by means of mixture No. 1, ethylidene chloride and methylene chloride in equal relations of volume, boiling point 50.5°, being especially well borne. With mixture No. 1 narcosis sets in rapidly, being easily kept up by small quantities of the drug; on inhalation ceasing awakening sets in sooner than with mixtures No. 2 and No. 3, the blood pressure and respiration having but inconsiderably slackened. Whereas blood pressure under chloroform falls on an average to 31.6 per cent to 68.1 per cent, during the cessation of reflexes, it falls to 5.4 to 12.8 per cent with mixture No. 1, and to 9 to 18.1 per cent with mixture No. 2, by the end of the experiment. The blood pressure with chloroform fell to 68.8 to 76.3 per cent.; with mixture No. 2 to 38.5 to 50 per cent. and with mixture No. 1 only to 22.6 to 28.7 per cent.

During narcosis produced by these mixtures, the breathing did not slacken, although a greater quantity of the narcotic was administered than in the case of chloroform.

Experiments with mixture No. 3, two parts of methylene chloride and one part of ethylidene chloride, boiling point 47°, have shown that, although having advantages over chloroform, it is inferior to No. 1 and No. 2; with mixture No. 3 breathing and blood circulation slacken sooner than with the first two mixtures which probably depends on the greater quantity of chlorine entering into the composition of mixture No. 3 as compared to the first two mixtures. Whereas with mixture No. 1 the blood pressure fell to 27.2 per cent by the end of the experiment (the experiment lasting one hour) twenty-eight grain of mixture No. 1 being used, 22.6 per cent, twenty and a half grains being used, and 28.7 per cent, thirty-five and a half grains used, it fell to 34.1 per cent with mixture No. 3, fourteen and a half grains of mixture No. 3 used, to 44.8 per cent, twelve grains of mixture No. 3 used, and to 72.9 per cent, nineteen grains of mixture No. 3 used.

The period of excitement with mixture No. 3 is longer and awakening does not set in so quickly as with mixtures No. 1 and No. 2; the experiments with the two latter once more confirming the importance of the boiling point of a narcotic or mixture of narcotics, it being especially favorable to narcosis for the boiling point of the narcotics to be between 45° and 55° C.

CONCLUSIONS

After experimental observations on narcosis of animals by ethylidene chloride, methylene chloride and their mixtures we may draw the conclusion that both of these haloid producing methane, while not inferior in narcotic power to chloroform, exceed the latter in point of rapidity of the awakening. And farther, while exercising a less paralyzing effect, as compared to chloroform, on the respiratory and vasomotor centres and on the heart, they also act less depressingly on blood circulation. Mixtures of ethylidene chloride and methylene chloride are preeminently deserving of attention, narcosis with mixture No. 1 being especially well borne.

Narcosis administered to human beings by the mixtures proposed by myself have yielded most favorable results.

Instruments, Apparatus, and Clinical Notes

SUBMUCOSA DISSECTOR*

A. J. Graham, M.D., F.A.C.S.
Chicago

This instrument is designed to facilitate exact dissection in those procedures in which habit has led the operator to use the end of the scalpel handle, or scissors, instruments which, obviously, are not uniform in size, shape, or degree of sharpness.

In devising an instrument to clear or expose the submucosa we must clearly recognize three facts, viz.:

1. That when the alimentary tube has been macerated for fourteen hours and scraped, there remains

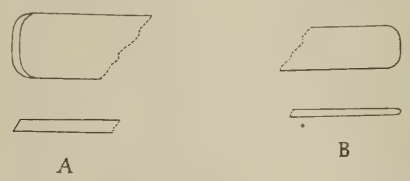

Fig. 1.—The ends of the instrument. Point A (large end) is beveled and the long edge, properly dulled, is directed against the leatherlike submucosa to scrape it clean without cutting. This is the novel feature in its use.

Point B. (small end) is a spatula dissector 7-32 of an inch wide with dulled end and rounded corners thus avoiding cutting, and facilitating finding the easiest cleavage plane. It also may be used in lifting the peritoneum from the ureter or separating adhesions.

a tissue, leatherlike in consistency, which is the skeleton structure supporting and connecting all the coats of the intestinal wall.

2. In cutting into the bowel wall from the peritoneal side the mucosa and its intimately associated submucous coat everts, or slides over the edge and protrudes around over the peritoneum—eversion of coats.

3. The zone of tissue which is lax enough to permit this sliding or eversion of coats is the loose connective tissue of the submucous layer immediately adjacent to the circular muscle. Since tissues of this zone are chiefly connective in function with no large vessels or nerves it is the natural plane of cleavage of the bowel wall separating the muscles and peritoneum from the subjacent submucous and mucous coats.

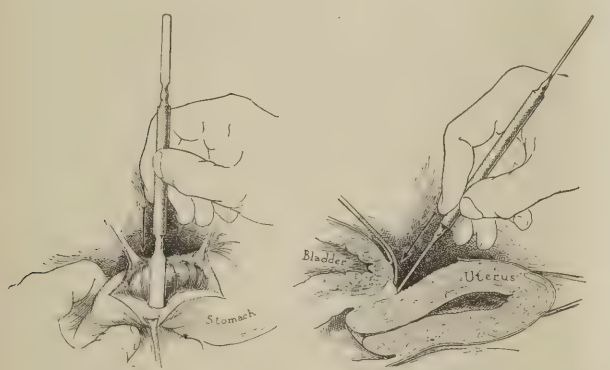

Fig. 2 Fig. 3

Fig. 2.—Showing the use of the instrument in congenital pyloric stenosis. Point A directed against the submucosa removing the hypertrophied pyloric sphincter muscle. Its dull edge will not perforate the duodenal submucosa.

Fig. 3.—Use of instrument in hysterectomy. The edge of point A is directed against the hard uterine muscle tissue thus avoiding injury to the peritoneum and bladder wall.

*From the Department of Surgery, College of Medicine, University of Illinois.

Fig. 4 Fig. 5

Fig. 4.—Point B, splitting the bowel wall in enterostomy.

Fig. 5.—Showing use of instrument in cholecystectomy. Point B, separating the gallbladder from its bed and isolating the cystic duct. The clamped cystic duct has been rotated to the left thus exposing the vessels for ligation before they have pierced the gallbladder walls, and while these vessels are still subperitoneal only and easily accessible. Point A is used from above down to clear the gallbladder of liver tissue.

The present instrument in a manner comparable to the back of a knifeblade readily separates the wall at this plane, where eversion of coats takes place.

A NEW RELOADING NEEDLE FOR THE IMPLANTATION OF RADIUM EMANATION IN CAPILLARY GLASS TUBES

Paul E. Durham, M.D.
New York.

The trend of radiology clearly indicates that the future will depend on the development of the technic of implantation of radium emanation in capillary glass tubes. But as the marksman must depend on the accuracy of his shooting iron, so must the radiologist be supplied with an implant needle free from mechanical faults. The following is a description of a new needle devised and used by myself to overcome the objectionable features possessed by other implantation needles so far in use.

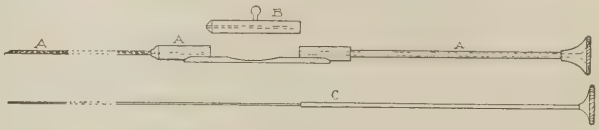

Fig. 1.—The hollow needle.

Fig. 1 illustrates the hollow needle, A, with cartridge B loaded with a radium seed ready to take its position in the chamber of barrel A, while C is the plunger used to force the seed from B through the barrel A and expel it at the needle point into the tissues.

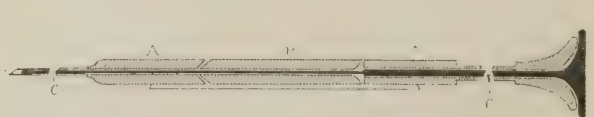

Fig. 2.—A schematic sketch of the needle with the cartridge in place.

Fig. 2 is a schematic sketch showing the needle complete with the cartridge in place which is pre-

vented from being removed by the plunger being driven up. The plunger C must be withdrawn beyond the cartridge B before this cartridge can be removed for the reloading of the following one.

Fig. 3A shows a cross section of a cartridge

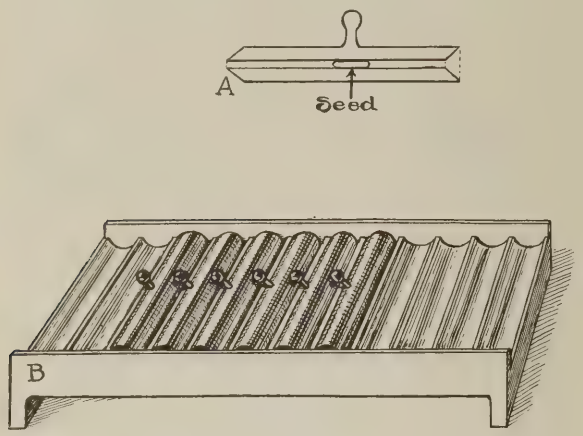

FIG. 3.—A, cross section of cartridge with a capillary glass tube ready to be placed in rack B.

loaded with a capillary glass tube of radium emanation ready to be placed in the rack 3B for sterilization by boiling preparatory to implantation or transportation to the place of operation.

Each cartridge is so made that the concave cone at the upper end acts as a guide to the plunger entering from the needle stock A while the convex cone at the distal end is in apposition with the upper end of the needle barrel A, this forms an uninterrupted channel for the route of the seed.

Fig. 4 illustrates the correct method of introducing several reloading needles in parallel and ordinarily about one centimetre apart with a subsequent deposit of seeds three quarters to one centimetre apart in the puncture channel left on withdrawal of the needle.

The cartridge, loaded with a bare glass tube of radium emanation, is placed in the chamber of the needle which has been inserted to the desired depth in the tissues. The plunger is forced forward expelling the seed at the needle point, the plunger is withdrawn

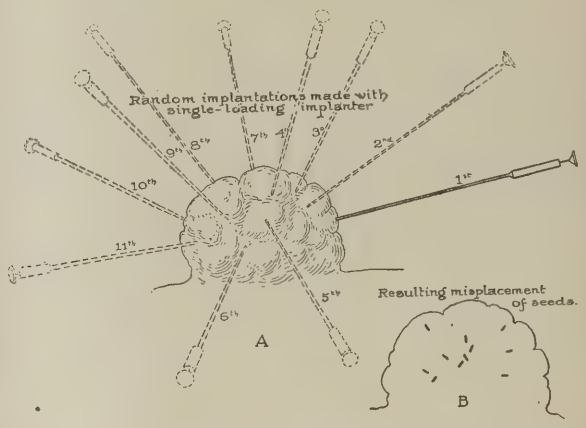

FIG. 5.—Faulty implantation resulting from the use of a single loading implant needle.

and the empty cartridge is removed, another loaded one is slipped into place, the needle is withdrawn about one centimetre and the plunger forced forward expelling a second seed in the puncture channel, etc.

Needle 3 in diagram 4B has been withdrawn the proper distance and the loaded cartridge is being introduced for the implantation of the last seed.

By the introduction of several needles at a time in a specified section of the neoplasm the operator is aware of the relation of the inserted needle points and thus avoids "bunching of seeds" or the deposits of them sparsely or not at all in other sections of the growth. This faulty implantation of a tumor involvement occurs when each seed is deposited by the insertion of an individual needle or "single loading

Fig. 4-B

implant needle" as seen in 5A. Should the case call for the embedment of a large number of seeds (in some cases in the neighborhood of eighty or ninety), it is apparent that this greater number of needle punctures is accompanied by excessive trauma, hemorrhage, the more likelihood of introduction of infection slough and possibly serious sequelæ. A faulty distribution of seeds results in sections of the neoplasm and surrounding tissues receiving excessive radiation with a resulting necrosis while other parts will be mildly radiated and left to produce the socalled recurrence (Fig. 5B).

The length of the needle shank for ordinary implantation is ten to twelve centimetres. But different lengths may be attached to suit the case in hand as well as flexible needles for the introduction through instruments more particularly the cystoscope. Several needles with two dozen cartridges are a practical working set.

The history of implantation needles is a brief one. Duane is credited with having been the first to suggest this method of burying radium emanation confined in small capillary glass tubes in the substance of the neoplasm. The deposit of each seed in the tissues required a separate puncture by an individual needle. Flexible and curved needles were devised with various types of handles attached following this, but not until 1923, did anything new in the way of an improvement appear. Muir, at this time, described a needle in which the seeds were placed in a slot in the barrel. Although slot reloading needles are a great advantage over the single seed needle they do not fulfill all the requirements which are essential for implanting a large number of seeds accurately in quick time under adverse circumstances.

ADVANTAGES OF NEEDLE

Advantages of the reloading cartridge needle are: 1, uniform and equidistant distribution of seeds is obtained; 2, the time of implantation is reduced to one quarter or one fifth that required when other types of implantation needles are used—this is especially to be preferred in those cases where a general anesthesia is used; 3, the trauma from the use of the reloading needle is reduced on the average from one quarter to one fifth that produced by the single loading needle; 4, the action is automatic, there is no jamming of seeds (the cartridges are either loaded and sterilized previous to the beginning of the operation or are loaded on a side table by the assistant after they are emptied); 5, there is no chance to drop "live seeds" into the abdomen or other vital locations while reloading; 6, there is no hindrance to implantation when fluid from a cavity or blood from vessel puncture returns through the needle; 7, the more inaccessible neoplasms are implanted with less difficulty; 8, all parts of the instrument are easily sterilized; 9, the metal of the cartridge acts as a filter to protect the radiologist's hands from accumulative radiation effects.

AN AUTOMATIC TRANSFUSION APPARATUS MADE FROM AN ORDINARY EAR DOUCHE*

SAMUEL GORDON BERKOW, B.S., M.D.
Perth Amboy, N. J.

So many automatic transfusion apparatuses have been devised lately that only special considerations prompt the present report. A very good automatic transfusion apparatus can be made from an ordinary return flow ear douche. Such an apparatus has even certain advantages over the expensive automatic transfusion apparatuses now on the market. It is of all glass construction and operates by means of a single ball valve, instead of by two such valves, as automatic transfusion apparatuses now sold possess. In addition to these advantages, the materials for the apparatus herewith described are readily obtainable

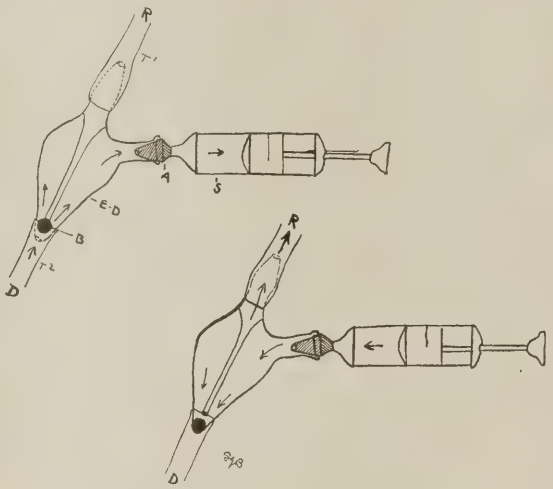

FIG. 1.—E-D, return flow ear douche; A, Luer-Record adapter; B, metal ball; S, 2 C.C. record syringe; T1, rubber tubing; T2, rubber tubing (catheter end)); D, donor; R, recipient.

everywhere; and it can be constructed very simply, in a few minutes.

In addition to the ear douche only a Luer-Record adapter and one ballbearing are required—beside the usual requirements for transfusion, i. e., a hypodermic syringe, two pieces of rubber tubing, needles or cannulas.

The aural end of a return flow ear douche is heated in an alcohol flame, or a Bunsen burner, until it is slightly drawn out. A glass bead or the metal ballbearing is dropped into this opening. The ball should fit loosely. The aural end of the ear douche is now flamed again, until it is drawn out one eighth inch below the metal ball, and the mouth of the tube is flamed until it is sufficiently closed to prevent the metal ball from dropping out. The chief precaution in making the apparatus is to flame the mouth of the ear douche evenly. The Luer part of the Luer-Record adapter is inserted into the outflow tube of the ear douche, and the surrounding glass is then flamed until the adapter is held tightly.

To the aural end of the douche, about six inches of rubber tubing is fitted; and a needle or cannula attached. This is to go to the donor. To the inflow

*From the Zelda Gordon Berlow Memorial Maternity Hospital.

end of the ear douche a similar piece of rubber tubing, with the needle or cannula, is attached. This goes to the recipient. To the Record adapter at the outflow tube of the douche a hypodermic syringe is fitted. This completes the apparatus.

TECHNIC

The action is as follows: When suction is made with the syringe, the glass or metal ball is raised, opening the tube leading from the donor, while it closes the small inner glass tube which leads to the recipient. When the syringe is emptied, the pressure forces down the glass or metal ball, closing the path to the donor, and leaving open the glass tube which leads to the recipient.

Ear douches are made in three sizes, small, medium and large; any size is suitable for transfusion. The size selected depending upon the diameter of the metal bearing which is available. The size of the syringe used varies with the size of the ear douche. With a large size of the ear douche a two c. c. syringe should be used; and with a smaller size a syringe of correspondingly *greater* capacity is advisable.

In using the apparatus it is best to have the recipient's arm at a somewhat higher level than the donor's. This can be accomplished by placing a pillow under the recipient's arm. Holding the apparatus in the left hand, with the needles or cannulas in place, it is filled with saline. By downward pressure of the syringe piston all air bubbles are expelled, and the rubber tubes to both donor and recipient are clamped with small "bulldog" clamps. The needles or cannulas are then inserted in the brachial veins of patient and donor in the usual manner. The clamps are removed, and the down stroke of the syringe piston is completed, injecting the saline. The transfusion then proceeds simply by pumping the syringe piston.

ADVANTAGES OF APPARATUS

The advantages of such an apparatus to the physician or surgeon (or small institution), who uses a transfusion apparatus only on rare occasions, and who may therefore be very reluctant to spend a large sum for an automatic apparatus, are obvious. But there are additional advantages. The blood which goes to the recipient is blood, *not from the syringe,* but from the glass barrel of the ear douche. The presence of air can therefore be detected far in advance of its passage to the patient. The single ball valve, instead of two, has the obvious advantage of simplification.

The long, narrow, inner tube, which provides a channel to and from the recipient, is a very great advantage. It further eliminates the risk of back flow from the recipient to the donor. Since luetic patients may need transfusion, this second precaution against back flow from the recipient (the first is the ball valve) is important.

Undoubtedly, improvements may be made in this apparatus by slightly modified special construction, better glass, etc.; but it is simply the purpose of this paper to show that a very good automatic transfusion apparatus can be made from an ordinary return flow ear douche, in a very short time and by very simple methods.

138 Market Street.

Arthroplasty Splint.—Paul N. Jepson (*Surgery, Gynecology and Obstetrics,* October, 1925) describes a splint used at the Mayo clinic which has proved very satisfactory after arthroplasty of the hip or knee. Immediately after the operation a Buck's extension is applied to the leg, and then a light cast or a posterior gutter splint. At the end of five days this is removed, and the arthroplasty splint, made of aluminum with a joint lock to prevent hypertension at the knee, is applied. To the upright footpiece is fastened a rope running over pulleys on the overhead frame, and to the rope is attached a six pound weight. This part of the apparatus prevents rotation of the leg on the thigh, or rotation of the thigh in the hip. A roller beneath the footpiece prevents friction on the bed clothing and operates on a short board placed on the bed. A Buck's extension is placed on the outside of the footpiece to permit continuous traction on the knee or hip. Straps are applied to the splint to hold it firmly to the extremity. Ropes are connected with a hand hold, so rigged that the patient, by pulling on it, can move the knee joint as often and as much as can be tolerated. After arthroplasty of the hip a special abduction Bradford frame is used in order to afford sufficient bed surface on which to operate the splint.

Elastic Adhesive Plaster.—Edward Lilienthal (*American Journal of Surgery,* September, 1925) describes an elastic adhesive plaster to take the place of the usual forms of adhesive plaster in securing compression and support. The new material consists of a rubber and cloth webbing with adhesive mass applied to one surface; it stretches more than double the original length. The author's first experience with this plaster was in cases of thoracoplasty after the external wound had healed but before the resected ribs had solidly united; even pressure was secured for as long as three weeks without change. Other uses have been in pleurisy, in fracture of the ribs, in cases of abdominal section where there has been distension, and as a support in visceroptosis. It has also been used for ambulant patients in suppurating wounds of the groin, as it does not prevent walking. It should not be used ordinarily in dressing fractures or in strapping sprained ankles.

The Kahn Precipitation Test.—William Levin (*Northwest Medicine,* December, 1924) tried out the Kahn test as a check upon the Wassermann in the laboratories of the Kansas and Oregon State Boards of Health and presents the following conclusions: 1. Parallel Kahn and Wassermann tests made on 2,542 blood specimens submitted to the Oregon State Board of Health Laboratory showed complete agreement in 92.2 per cent., fair agreement in 2.3 per cent., and complete disagreement in 5.5 per cent. 2. The Kahn test was more sensitive than the Wassermann test in 71 treated cases for which complete data was available. In this series 55 Kahn reacting tests gave 26 negative Wassermann tests, while 45 Wassermann reacting tests gave 16 negative Kahn tests. 3. In primary syphilis the Kahn test became positive practically at the same time as the Wassermann test. 4. Because of its simplicity and high degree of accuracy the Kahn precipitation test should be adopted as a routine test in the diagnosis and treatment of syphilis, supplementary to the Wassermann test.

Symposium on Preclinical Signs of Disease—II.

Medical Journal and Record

NEW YORK, WEDNESDAY, NOVEMBER 4, 1925

Infections, Infectious Diseases, and Immunization*

WILLIAM H. PARK, M.D.
New York

My subject is a little out of the direct line of these lectures, but I am not responsible for that, and I am glad to have it in. I shall not speak of infectious diseases as forms of sickness in themselves, or of their direct effects on the heart, arteries, kidneys, nervous system and other parts of the body, for they are fully covered by other lecturers. I shall present the modern views regarding the value of sera and vaccines in preventing diseases.

You will realize that the two forms of the immunizing injections which we use are vaccines themselves, and sera from animals that have been vaccinated. The protective substances in the sera being from animals with different blood constituents from man, the immunity is not lasting. The antibodies in the sera that destroy the bacteria last only a few hours or a few days, while the antitoxin injected with the serum lasts a few weeks.

Vaccines are either living or dead. The first vaccine used was, as you know, the living virus of cowpox. This was a natural attenuated virus. Later the living virus of rabies and anthrax was deliberately attenuated by drying and heat, and later we began to use vaccines of dead bacteria, and the toxic substances produced by them in the media, so that the word vaccine passed first from the cowpox to the attenuated rabies and anthrax, and then simply to any inoculation which actively protects.

We all realize that in using vaccination for a definite disease, we necessarily must know the type of organism causing that disease, or that we have at least the same microbe; and a disease like diphtheria, or typhoid, or scarlet fever, or smallpox which is due to a single type organism is very much simpler to attempt vaccination in than a disease like lobar pneumonia, in which, although due to the pneumococcus in nearly every instance, is due to a number of types of pneumococci, and those types are so distinct that immunization against one type gives little protection against another type; and when we come to bronchial pneumonia, there we not only have different types of pneumonocci, but also streptococci, and a number of other organisms.

*Read at the New York Academy of Medicine, on January 8, 1925, as part of a symposium on preclinical signs of disease, under the auspices of the Medical Society of the County of New York.

So that when we begin to think of immunization with bacterial vaccines, we always must ask, Is the disease that we are going to try to immunize against a clear cut entity, due to a single type of organism? Or is it due to several types of the same class? Or is it due to many different varieties of organisms?

We know that certain vaccines are effective, such as those against typhoid fever, cholera, smallpox, diphtheria, and I think we can add scarlet fever. Others are only moderately effective, like the pneumococcus infections and those due to influenza bacilli, and to the whooping cough bacilli.

I shall touch on a few of the most common vaccines and hope perhaps to bring up a few practical points with which you are not very familiar.

TYPHOID FEVER

As to the typhoid vaccine, we have all been interested in that recently, because of the outbreak of typhoid which we believe to have been due to oysters. We might take a moment to say why we believe that. When we look at the water supply of this city we find that there is no relation between the typhoid fever and the water supply, absolutely none. When we look at the milk supply we find absolutely no relation. When we have eliminated the water and the milk, we have practically confined the possibilities to oysters and green vegetables.

It is an interesting thing (I think I am right from what I have been told) that the Italian population eat a great deal of green vegetables, and they are peculiarly exempt from this typhoid outbreak; while on the other hand we find that typhoid is mostly in the residential district where people of greater means live, who are used to eating oysters. We find that people in Chicago, and in Rochester, and in Buffalo, and Syracuse and Philadelphia, who have had oysters from the New York oyster district, have suffered from a considerable excess of typhoid fever, and we find that fully seventy per cent. know that they have eaten raw oysters within the time; and then curiously we have some places like Baltimore, where there is a slight excess, and we find a marked percentage of those have been visiting New York.

As to whether we should vaccinate or not. The question of whether we should use typhoid vaccine

or not must be decided on the question of whether the definite immunity which is recognized to be due to the typhoid vaccine is worth the annoyance and expense of the inoculation, and each physician must decide for his patients that question. We have much information as to the value of typhoid vaccine.

We know from our own results of vaccination before the war. When the men went down to the Texas border, they had been vaccinated with typhoid bacilli, but not paratyphoid A or B, and there were only one or two cases of typhoid among all those men, but many cases of paratyphoid A. There was a clinching argument, because if they came in contact with paratyphoid A they must have come in contact with typhoid infection.

Then you know the result of the great war. I was there a few weeks in Paris in 1917, and they showed me the records, how before the French troops were vaccinated, because they were called out in such an emergency, the typhoid cases ran up to five or six hundred a day. Then when they were vaccinated, typhoid almost disappeared. From that and the evidence of individuals we know that typhoid vaccine given in three injections does give a marked immunity for two years, and a considerable immunity for three years.

We continue, as a rule, to use the triple vaccine because you can give the three organisms, the paratyphoid A and B plus the typhoid, with only a moderate amount of increased reaction. If you mind the excess of annoyance and believe there is little chance of paratyphoid infection, you can give the single typhoid vaccine.

If the first injection should give a marked reaction, it is wise to give another dose of the same size instead of doubling it, and then add two more half doses. Or, if you want to be very cautious, you can halve the first dose and then give one half a c.c. at the second and third, and the fourth a full dose. In that way you will cut down the reaction. The more the dose to be injected is divided to make additional injections, the better the response. There is no promise that any one can make that if the first injection does not give a reaction, the second or third will not. As a rule, the second and third are less, and the second is not as much as the third.

We cannot promise that the first injection made years ago having been without annoyance, that a new one now will be. There is a vast difference in the individuals as to whether the first and second inoculation series shall be alike. I know one friend of mine who passed through the first series of inoculations without annoyance, but had a severe reaction from the second series five years later. Those who have been injected should continue to take reasonable precaution because the protection is only slight in some.

There are several methods of performing a vaccination for smallpox— the scratch of an eighth of an inch with the rubbing in of the vaccine, the three or four punctures with the needle through the vaccine, the intracutaneous inoculation, and the subcutaneous.

We prefer, from the health point of view, the tiny scratch of an eighth of an inch, because that makes definitely a moderate scar. You seldom get a large scar if the vaccine is rubbed into so small a scratch. If you make punctures, they don't always give definite scars, and it is hard to show years afterwards, when the children go to school, whether they have been vaccinated definitely or not.

The same thing is sometimes true of the intracutaneous method. The subcutaneous method, I think, is decidedly to be objected to because you are not at all sure whether you have had a vaccination or not, and, of course, you also have no scar unless you get a vaccination at the point of puncture.

With the regulations enforced for the past ten years, nowhere in this country has any vaccine been found to contain tetanus, nor has any vaccine in capillary tubes been shown to produce tetanus on vaccination. We have not had for three years any case of tetanus following vaccination in New York city. Over a series of years we have possibly one a year on the average, but in every case the tetanus has come at such a date and usually under such conditions that you could positively say that the tetanus infection had occurred in the child after the development of the vaccination.

It is impossible to promise absolute immunity for more than one year; therefore, in the Health Department we have the rule that after any direct exposure, a person not successfully vaccinated should be vaccinated again if more than a year has elapsed. If they are immune, there is no annoyance from the vaccination, and we get what we call an immunity response within twenty-four hours, a slight beginning reaction which disappears after another day. Unless there is a direct exposure or the presence of an outbreak, a five or even a ten year period between vaccinations is suitable. Vaccine virus should be kept in a cold place.

DIPHTHERIA

The prevention of diphtheria. That disease kills more and maims more people than typhoid fever, and yet while the general practitioner will use typhoid vaccine freely and with enthusiasm, it is difficult to get the physician to use the diphtheria toxin-antitoxin. It is interesting the way the work that we started in New York has spread, so that instead of being in the forefront of using toxin-antitoxin to immunize, we are getting behind a number of other cities.

The diphtheria mortality and morbidity after dropping in the last four years to one half of the deaths and two thirds of the cases, have slightly increased, and we expect to have one hundred more deaths this year than the year before.

I had one hundred and fifty consecutive children looked up a few weeks ago and found that only three of those children had been Schick tested or given toxin-antitoxin. Two had been given toxin-antitoxin and one other had been Schick tested. All the others had not had any immunization, so that certainly there is no reason to say that it was in spite of immunization that such a considerable amount of diphtheria occurred, but rather because it had not been done. Of those two in whom diphtheria developed who had had the toxin-antitoxin, both were so mild that it was doubtful whether the condition was diphtheria or not. We know that only about eighty-five per cent. of the first series of inoculations produce immunity in children. The best men find no trouble in getting the mothers to consent to it, and often they have their enthusiastic cooperation; so that I hope that we may all be more enthusiastic

about using the toxin-antitoxin, either with or without the Schick test.

Of course the Schick test is somewhat technical, but any of us, with a little salt solution and practising a few hours, could become skillful in giving an intracutaneous test, or if we prefer we can give the toxin-antitoxin just under the skin in the arm above the elbow. Give one c.c. of toxin-antitoxin subcutaneously and you get the same result as with the Schick test. Dr. Schroeder is using that method entirely in the Brooklyn schools, and we are going to start in Manhattan by giving one c.c. subcutaneously, not deeply, but superficially. We get a reaction exactly like the Schick test only about four times as great in extent. If the reaction is positive we continue the injection, while if negative we discontinue them or give a second only.

There will be a few more positive reactions that way than with the Schick test. In that way you can simply give the three injections and the first injection will show whether the other two are needed or not, and that may make it easier for physicians to use. It is simply a strictly subcutaneous injection.

SCARLET FEVER

As to scarlet fever, we have all read in our medical papers recently of the work. It is interesting to look back and think that it has been thirty years since the first work in scarlet fever was done, and that in 1906 Gabritchewsky definitely showed that the streptococcus from scarlet fever made a toxin which when injected in sufficient amount caused scarlatina rashes in those who had not had scarlet fever, and made no scarlatina rashes when the vaccine was given in those who had had scarlet fever. He stated that the work done before by Moser and the older bacteriologists, plus his work, definitely showed that the scarlet fever streptococcus made a peculiar toxin, which, while it did not affect animals, caused the rash in man. He vaccinated some seven hundred children and his colleagues many thousands more, and they assert that in the lack of infection after exposure these children showed that immunity had been produced.

Recently the Dicks tested the filtrate intracutaneously, the same as in the Schick test for susceptibility to diphtheria, and they found to their great interest that the toxin which has no specific effect in small animals does show in man whether a person is immune or not to scarlet fever. Three volunteers, who showed a positive Schick test, were inoculated, and in them there developed scarlet fever. Thus, this more clearly established the conclusions of the earlier investigators that a special hemolytic streptococcus was the cause of scarlet fever.

In our laboratories Dr. Zingher has tested a great many children in several schools in which scarlet fever was developing, and in eleven of those children that had had positive Dick tests scarlet fever developed and in none of the children that did not have a positive test; so we feel, although it has not yet been proved, that the Dick test will rank with the Schick test as a detective of immunity.

We also have now a potent serum, and we are ready to give that out to any who have toxic cases. There is no need of giving it in mild cases.

We all know that scarlet fever has diminished enormously in its intensity and somewhat in its prevalence, and yet its aftereffects are so important, and the long isolation and annoyance are so great that I think people will be even more ready to have the Dick test done and the toxin given than for diphtheria. We don't use toxin-antitoxin because the streptococcus toxin is so mild in its effects that you can use it directly.

BUBONIC PLAGUE

Just a word or two on several other diseases. A great many questions were asked by people as to whether they should go to California when the outbreak of pneumonic plague occurred a few months ago; and we were also asked sometimes whether they should be vaccinated. The evidence so far is that vaccination against the bacillus of the bubonic plague is effective for the mildly virulent infection; but when you have the most virulent type, it is ineffective. That was worked out by Stong and Teague in the Manchurian outbreak.

PNEUMONIA

Pneumonia is a disease of the middle ages of life, one of the mostly deadly diseases we now have. If we could only immunize efficiently and practically against pneumonia we would all feel like doing it. The literature is, on the whole, rather enthusiastic for the immunization against lobar pneumonia, if you can use vaccine of the types of pneumococci that are causing the pneumonia. You will remember that in New York about half of the cases are due to type one; about a third are divided between type two and type three; and the rest are due to type four. Sometimes the type one would be only a quarter and there would be more of type four. We can't hope to immunize against type four, because, as you know, type four is not type four, it is four, five, six, forty—it is all the rest, and for convenience we call it type four. All we can do is to do it against types one, two, and three, which are generally about two thirds or three quarters of the cases. We have tried vaccines quite a bit in New York to test this out.

We first got fifteen hundred volunteers in the Metropolitan Life Insurance Company, and for about six months after immunization the results seemed good—only one case of pneumonia occurred among the fifteen hundred, while eleven cases occurred among the three thousand controls, which made it a little more than five to one, and then in the next few months, several of those vaccinated developed pneumonia, so it seemed that protection against these fixed types of pneumonococci was considerable for about six months. The question remains, is it worth while to be vaccinated every six months against the possibility of lobar pneumonia?

We than transferred our work to the physically well patients over on the Island. The Metropolitan Life Insurance clerks did not note enough protection to be enthusiastic over repeating the vaccination. For three years we carried out there the giving of half of them vaccine and half not. The results there were disappointing. Most of the deaths were from type four pneumococci, and few straightout lobar pneumonias were due to types one, two, and three.

After three years, although over there the physicians felt we had done a great deal of good, we could not see from careful figures that we had accomplished much. The good, I think, was imagined rather than real, because we had excluded the very

bad and very sick cases, and, of course, they were by the physician recorded as unvaccinated.

A pneumonia vaccine is a perfectly sensible thing to give, but hardly a public health measure to urge.

WHOOPING COUGH

Whooping cough is much the same. The results that we have had have shown this. We have been immunizing the children in a large number of institutions and keeping a large number of other institutions as controls, and the difference has been only moderate in favor of the immunization.

Dr. Madson, as you know, has been over here and he gave a lecture showing how in one of the islands where whooping cough had not come for many years, it spread over the place, and they gave the whooping cough vaccine and almost as many cases developed, but only in a slight form, and he thought that that demonstrated that the whooping cough vaccine had immunized the population. I am not sure, because it is hard for me to conceive that an immunizing agent would slightly immunize all, but not completely immunize any. As a rule, some are much immunized, some somewhat, and some not immunized. My own experience has not been extremely encouraging; but it is probably worth giving, and may have some effect.

COMMON COLDS

My results with vaccine against common colds is similar. At the Metropolitan Life Insurance Company, we gave a polyvalent vaccine against common colds. It was a mixture of influenza bacilli, streptococci and three other varieties, the usual shotgun vaccine against common colds. It must be remembered that those who volunteered were undoubtedly those who were likely to have colds, and those who did not volunteer were probably those who did not usually have colds. At the end of the winter there was little difference between those who had the vaccine and those who hadn't; and when we came to the next year, only seventeen of the fifteen hundred offered to be vaccinated again. In my opinion there was little effect from the vaccine.

Diabetes Mellitus, Preventive Measures and Early Diagnosis*

HERMAN O. MOSENTHAL, M.D.
New York

INCREASING OCCURRENCE OF DIABETES MELLITUS

The incidence of diabetes mellitus in the United States and other countries is distinctly increasing. In the registration area of the United States during the last forty years the death rate per one hundred thousand of population from diabetes has risen from 2.8 to 16.6, while the death rate from all causes diminished during this period; in 1880 deaths from diabetes were 0.14 per cent. of all deaths, in 1921 the proportion had risen to 1.4 per cent. This increase in the diabetic mortality has been constant from year to year. In New York City the diabetic death rate has grown greater from 1866 to 1923; in 1866 the proportion of diabetic deaths to all others was one to 2,437, in 1923, one to fifty-one. Diabetes in the United States now stands twelfth in numerical order as a cause of death. A recent article by Dr. Haven Emerson and Dr. Louise D. Larimore (1) furnishes many of the facts and figures I am quoting in this and other sections.

What is the significance of this rise in mortality rate? It has often been surmised that our methods of diagnosis are more efficient and that our knowledge of derangements in carbohydrate metabolism is more accurate and that consequently cases are identified today that would have passed unrecognized some years ago. This may be true of the earlier stages of the condition, but not of the terminal ones, in which a simple urine analysis readily reveals the true state of affairs. Consequently we may regard the mortality rate as indicating the real incidence of the disease. This shows that diabetes mellitus has increased enormously in the past forty years.

*Read at the New York Academy of Medicine, January 27, 1925, as part of a symposium on preclinical signs of disease with special reference to the management of the health examination, under the auspices of the Medical Society of the County of New York.

OVERNUTRITION

The cause of the more frequent occurrence of diabetes has been ascribed to the more plentiful food consumption associated with the advancing prosperity and higher standards of living in all civilized countries. Thus Legendre estimates that in France, in the year 1832, 1,645 calories were consumed per capita; in the year 1862, 2,245 calories were consumed per capita; in the year 1912, 3,160 calories were consumed per capita. The same is true of other nations.

As sugar has grown cheaper and more plentiful, it has been consumed in larger quantities and added much to the caloric value of our diets. The study of sugar consumption and diabetes shows that they increase or diminish in direct ratio. The changes occurring during the war are striking (Table I).

TABLE I

RELATION OF DIABETIC DEATH TO SUGAR CONSUMPTION

Country	*Year*	*Diabetic death rate per 100,000*	*Pounds sugar consumed per capita*
France	1890	13.5	28.9
	1913	16.0	43.8
	1918	9.6	13.3
Great Britain	1890	6.5	58.9
	1913	11.8	78.5
	1920	10.0	45.0
United States	1890	5.5	54.5
	1922	16.8	103.2

The occurrence of diabetes is not to be ascribed to the sugar alone, but to the increase in our total number of calories. Furthermore, a person leading a sedentary life can not cope with the same amount of food successfully, as one who is exercising constantly. Too little physical exertion coupled with a liberal diet leads to obesity and the combination tends to diabetes mellitus. Dr. Joslin has given us serious warnings concerning excessive gain in weight as a factor in the

production of diabetes for some time. The evidence thus far brought forward is certainly in favor of this conception. It is interesting to note that the increased incidence of diabetes is in the age periods above forty-five, a period in our existence when we are prone to be less active and eat more when compared to previous generations.

It must be understood that overeating and obesity are not the only factors concerned in the production of a diabetes. There are many very obese individuals who do not suffer with glycosuria and never will. In addition to the strain put upon the bodily functions by food excesses, there must be a diminished tolerance for carbohydrates—a lowered internal secretory power of the pancreas, as we believe diabetes to be. Under these circumstances diabetes is extremely prone to develop.

Overeating, an absolutely sedentary life and obesity are noxious factors. The death rate of the obese individual above forty-five years is known to be high and the life insurance companies do not favor him as a risk. From the point of view of general health and especially of potential diabetes physicians must most seriously council proper diet and exercise as prophylactic measures in everyone.

HEREDITY

There are carefully worked out family trees for diabetes showing how the disease may without doubt be hereditary in certain instances; in these families sometimes the condition shows a distinct tendency to occur at an earlier period in each generation. At present the hereditary factors are being discredited as applying to diabetes in general. It is argued that with the marked prevalence of diabetes it is not remarkable that a fairly large number of cases occur in families that have a diabetic ancestor. It may be true, too, that overeating, sedentary habits and obesity prevail in certain families, thus favoring the occurrence of diabetes among them. However true these suppositions may or may not be, a careful supervision of the children of diabetic parents is well worth the trouble. I know of one such instance in which the monthly examination of urine served to ferret out a diabetes at an early stage and thus furnished the indications for treatment at a time when they were of the greatest help.

NERVOUS STRAIN

It is true that nervous strain, whether of short or long duration, slight or severe, will disturb an existing diabetes. There are many instances in which an exacerbation of the condition was produced under these circumstances. Thus in a woman, who was very much shocked because her boy had an epileptic seizure, it required six months of treatment to restore the carbohydrate tolerance to the former level.

There is considerable doubt, on the other hand, whether nervous strain influences the onset of diabetes. During the world war among the soldiers, as well as among the civilians, diabetes diminished in frequency. The nervous strain was at a high point constantly for all concerned and yet the low diets of those days far outweighed the effects of the high nervous tension.

A diabetic should therefore be shielded from nervous strain.

SPECIAL CAUSES

We know little of the causes that affect the pancreas directly and bring about diabetes. In fact it must be admitted that in the majority of cases of diabetes, although we may feel certain that there is a pathological condition in the islands of Langerhans, yet the factor or factors bringing about such an anatomical change is unknown to us. There is one type of disease that should be considered in this connection and treated energetically in order to prevent diabetes. This is any obstructive state of the terminal portion of the common bile duct which would have a tendency to force the bile into the pancreatic tissue instead of allowing it to pass directly into the small intestine.

IMPORTANCE OF EARLY DIAGNOSIS

If the greatest good is to be accomplished for the patient the treatment must be begun at the earliest possible moment. There are many reasons why this should be considered most seriously. In all diabetics the presence of glucose in the urine signifies an overload of the bodily functions which utilize this material; in most of them this strain upon the sugar digestion results in a progressive loss of carbohydrate tolerance that very frequently can never be wholly or even in part regained. Hence early limitation of food so as to allow the urine to become sugar free and consequently the sugar utilizing functions to work within their capacity is urgently indicated. There are some diabetic patients in whom a trace or a small amount of sugar in the urine is not associated with a gradual increase of the severity of the disease. However, there is no absolute way in which the progressive and nonprogressive types of diabetes can be differentiated and it is to say the least unfair for the physician to gamble on these possibilities and be negligent of eliminating glycosurias energetically.

It is an established fact that a persistent glycosuria entails other penalties than a simple loss of carbohydrate tolerance. For some time it has been appreciated that the diabetic patient might not be particularly subject to a diminishing carbohydrate tolerance and yet die before his time of one of the complications of the disease. In neglected cases arteriosclerosis entailing gangrene, angina pectoris, contracted kidney, and other conditions, are almost sure to be present sooner or later; cataract, boils, carbuncles and constitutional infections may also be regarded among the common and serious complications. It is an open question whether the hyperglycemia has any relation to these states or not. There is no definite proof either for or against such a supposition. Personally I believe that the desiccation occurring in the body as the result of polyuria is the principal factor responsible for them. Some of our patients, in the days before insulin, with marked progressive furunculosis have been cured when the urine has been rendered sugar free and the polyuria abolished even though the blood sugar remained well above the normal level. The elimination of sugar in the urine therefore is important from another point of view; it sets aside a dryness of the tissues through the control of polyuria and thereby prevents secondary changes of a serious nature; among these we believe that arteriosclerosis and its sequelæ and various forms of infection are particularly important.

The early diagnosis of diabetes mellitus is of great economical importance from two points of view. In the first place proper treatment begun at the incipiency of the condition will prevent the loss of strength and physical and mental efficiency so frequently seen in neglected cases. Furthermore, a patient seen in the early stages can be readily controlled and taught the required steps in diet while carrying out his or her daily routine of work and relaxation. It is only in advanced, or rather, neglected, cases that money and time need be spent upon institutional care. It is a curious fact that frequently a patient whose diet has been properly controlled will have an exalted feeling of physical efficiency for several weeks or months when he takes the bit in his teeth and goes off on a carbohydrate bat; sugar appears in the urine, there is an increase in weight and the sense of well being alluded to above. This is wonderful for a short time and frequently lulls both patient and medical advisor into a false feeling of happiness and security until the time comes when the overstrained internal secretions of the pancreas can not keep up the pace any longer and a crash occurs; now polyuria, progressive loss of weight, ending in emaciation, marked diminution in physical vigor come about suddenly and make all concerned realize that the gentle and thoughtful directions which Naunyn, more than any other man, has formulated for us, have their purpose. The same phases of increased appetite, physical efficiency ending in catastrophe are the lot of the incipient case of diabetes mellitus that is not diagnosed and treated at an early stage of the disease.

MEANS FOR EARLY DIAGNOSIS

There is nothing that surpasses the availability of the routine urine analysis. In cases where there is a suspicion that diabetes may exist it should be performed once a month. The prevalent laboratories that carry out an examination for one dollar are a boon in this connection when a physician's own laboratory is not available. The analysis of urine by the patient under observation has not yielded satisfactory results in my hands; such amateur chemists as well as their families often appear to suffer from undue nervous strain. No general examination should be considered complete without a routine urine analysis.

If a socalled trace of sugar is discovered in the urine on life insurance examination or otherwise it is often a matter of the greatest difficulty to determine whether or not this is really present. There are several important factors to bear in mind in this connection: the normal human urine contains a trace of reducing substance, equivalent to as high a concentration as .05 per cent of glucose; this will usually furnish a slight reaction with the Fehling-Benedict test. To be certain of what constitutes a reaction for pathological traces of glucose is often very difficult.

It is much the better method of procedure to obtain other specimens and begin the tests over again. It is advisable under the circumstances to ask the person suspected of having glycosuria to eat freely of starchy foods, especially sugar on the day of the test. If only single specimens can be obtained they should represent the urine voided two hours after the heaviest meal; the specimen taken after the dinner in the evening serves well; the urine voided on arising, which is so often furnished the physician, is apt to be free from sugar (unless insulin is being used when it is more likely to contain glucose than the specimens representing the remainder of the twenty-four hour secretion). The most satisfactory method is to obtain the urine at about two hourly intervals throughout the day and a single specimen at night and test each sample for glucose. Traces of sugar may often be identified in such voidings that are lost to chemical means if tested for in a twenty-four hour sample of urine. The tests to be employed are the Fehling-Benedict procedure, fermentation with yeast, and the phenylhydrazine crystals.

If the urinary tests prove to be inconclusive, and they very often do so, the blood sugar should be resorted to. It is the general custom today to obtain the blood for this as well as other chemical tests while the individual is fasting, before breakfast. This method of procedure furnishes data that tell us what has occurred at time of the least strain upon the individual and I do not believe that they yield the most useful or important information for the physician who is attempting to make a diagnosis or regulate the diet. As far as the blood sugar is concerned it rises about two hours after breakfast to its highest level of the day, and subsequently maintains this value more or less until night. This is true of the normal individual or of the diabetic who is partaking of a diet more or less adjusted to his needs; when the diabetic eats food far beyond his carbohydrate tolerance the sugar rises in steplike fashion with each meal. If the blood sugar is .140 per cent. two hours or later after a breakfast rich in starches we may suspect that the sugar tolerance is lowered; if it is .150 per cent. or higher we may be certain of it. The custom of considering a blood sugar of .150 per cent. before breakfast as being normal either from the diagnostic or therapeutic point of view is erroneous and leads to many errors and misconceptions. A patient with a normal glycemia from .090 per cent. to .120 per cent. before breakfast may show an abnormally high blood sugar level after breakfast, and it is not probable that the diabetic will maintain his socalled normal blood sugar after his meals.

If a normal degree of glycemia exists two hours or more after breakfast we are fairly safe in believing that no diabetes mellitus exists. If the blood sugar is higher than .140 per cent. we can not be quite so sure of our ground. The same troubles in interpretation creep into the valuation of the socalled blood sugar curves or sugar tolerance tests to be detailed a little further on. To repeat: a normal blood sugar indicates an absence of a diabetic tendency, an increased concentration of glucose in the blood does not necessarily signify diabetes. The first part of this statement is readily agreed to, the second demands some explanation. The situation may possibly be summarized as follows: An increased blood sugar signifies a diminished carbohydrate tolerance, but every instance of lessened carbohydrate tolerance is not diabetes. This is a somewhat vague conception but it has its distinct place in clinical medicine. Through the efforts of many observers it has gradually come to be appreciated that there are a number of diseases or conditions in which the blood sugar is often raised. Some of these are hypertension, arteriosclerosis, nephritis, hyperthyroidism, exophthalmic goitre, hyperpituarism, gastrointestinal car-

cinoma, syphilis and commonly in many patients above fifty years of age, though they are apparently in good health. The difference between hyperglycemias and diabetes mellitus are two, a pathological one and a clinical one. From the pathological viewpoint it is accepted for the moment that in diabetes mellitus there is a degenerative and destructive lesion of the Islands of Langerhans; in the other forms of hyperglycemia the faulty utilization of glucose may be attributed to other internal secretory disturbances, some lesions of the pancreatic tissue or an unknown cause. From the clinical aspect there is a vast difference between diabetes mellitus and the other conditions with disturbed glucose digestion: this lies in the well established fact that diabetes is a progressive disease resulting in such a degree of diminished carbohydrate tolerance within a few years, in most of the untreated cases, as to render life no longer possible, whereas in the other states mentioned this is not the case. The problem of interpreting blood sugar under these conditions with mathematical accuracy becomes impossible. We can be fairly certain that a person with a normal blood sugar after a heavy meal is not afflicted with diabetes but we can not establish a diagnosis of diabetes simply because the blood sugar is high, neither can we deny it. The same holds true of the more involved sugar tolerance tests to be detailed subsequently. Under the circumstances all that can be done, and it should be done conscientiously, is to watch these cases carefully by urine analysis and blood sugar determinations from month to month and await developments.

SUGAR TOLERANCE TESTS

When all other means fail to determine the significance of transient or doubtful traces of glycosuria recourse may be made to the sugar tolerance tests.

One hundred grams of glucose are given the fasting subject and the urine collected at the end of two hours and again for the next twenty-two hours. A trace of sugar (up to 0.2 per cent.) in the first specimen and no sugar in the second specimen are supposed to indicate that no diabetes mellitus is present; higher amounts of sugar are supposed to make the diagnosis of diabetes. This was the method of carrying out this test before it was possible to resort to the determination of sugar in small amounts of blood.

Today a sugar tolerance test, properly carried out, calls for a number of urine analyses and blood sugar determinations. Control specimens of urine and blood are obtained from the fasting subject; one hundred grams of glucose are administered; subsequently at intervals of twenty, forty, sixty, and one hundred and twenty minutes after the taking of the sugar, the urine and blood are again collected. The normal results should be within the following limits: 1, the urine throughout should give no evidences of glycosuria; 2, the fasting blood sugar level should be below .120 per cent.; 3, the maximal blood sugar should be .160 per cent. or less; 4, the blood sugar should return to a level of .120 per cent. or less in two hours.

If such a blood sugar curve shows a prolongation beyond two hours and a higher maximal figure than .160 per cent. a diminished sugar tolerance is demonstrated. Unfortunately such a condition is not pathognomonic of diabetes mellitus, but may also occur in hyperthyroidism, arthritis, nephritis, gastrointestinal carcinoma, epithelioma and, even, in socalled normal persons. The only diagnostic value of the procedure lies in the fact that a normal curve in all probability indicates that there is no diabetes present.

A further valuable aid in clearing up the significance of glycosuria by these means is the demonstration of a lowered kidney threshold to glucose, below the normal level of .170 per cent. In such instances of socalled renal glycosuria the origin of sugar in the urine is explained in a vastly different fashion than in true diabetes. These patients usually do well and diabetes does not develop though they may constantly or intermittently exhibit a glycosuria; they should be watched, for the above statement that renal glycosuria is not significant of diabetes is not admitted by everyone.

From the statements above it may be gathered that the early diagnosis of diabetes is not always an easy matter; doubtful cases should be observed carefully for a long period before a final opinion is rendered.

Asthma and Preasthmatic Conditions*

ROBERT A. COOKE, M.D.
New York

By the words hypersensitiveness and allergy we mean to denote an abnormal clinical response to absorbed substances, and we consider that a response is abnormal when it is obtainable in but a small percentage of a species. A striking example is the rather rare occurrence of an acute reaction in an infant, following the ingestion of egg and manifested by swelling of lips, tongue, and face, vomiting, pudging, dyspnea, cyanosis, urticaria, and collapse, whereas, egg is a perfectly natural and wholesome food for most infants. In the abnormal response these symptoms occur so immediately and so violently on contact with the smallest conceivable fraction of an egg that it is evident the trouble lies not with the egg but with the child who has developed peculiar reactivities. These reactivities constitute allergy.

The substances to which a case may be allergic gain entrance to the body in the following way:

1. Through the respiratory mucous membranes. (Inhaled substances, such as air borne dusts.)

2. Through the gastrointestinal mucous membranes. (Ingested substances, as foods or drugs.)

*Read as part of a symposium on preclinical signs of disease at the New York Academy of Medicine, January 27, 1925.

3. Through the skin. (Drugs externally applied or the poison of ivy or subcutaneous injections for therapeutic purposes.)

4. From foci of chronic infection.

The clinical manifestations of allergy are many and vary with the tissues that happen to be reactive. These tissues are essentially those of epiblastic origin, the skin, the mucous membranes of the upper and lower respiratory tract, and the mucous membranes of the intestinal tract. The following are the usual manifestations of allergy:

1. The skin manifestations are urticaria and angioneurotic edema, eczema, dermatitis of various forms, vesicular, as ivy poisoning, erythematous and papular.

2. The mucous membrane reactions in the upper respiratory tract give rise to symptoms of hay fever. When the attack is seasonal and the reaction is to pollens, it is true hay fever, but when it is paroxysmal or perennial and the reaction is to sachets, dust, feathers or dander, it gives rise to the clinical condition known as vasomotor rhinitis. These conditions are more accurately designated allergic coryza of seasonal or perennial type.

3. When the reaction occurs in the bronchi, we have the clinical symptom asthma. Reactions also occur in the pharynx, larynx, and trachea, and give symptoms peculiar to irritative conditions in those areas.

4. The hypersensitive conditions of the mucous membrane of the alimentary tract may give rise to acute reactions—acute food allergy already described—or the symptoms may be confined to a portion of the tract and give rise to gastrititis, enteritis, or colitis. In some cases the manifestations of the food allergies are not acute and merely lead to evidences of mild disturbance, as anorexia, undernutrition, nervous irritability, and sleeplessness. When these symptoms occur in childhood the children are below par in weight, bone and muscle development, and mental activity. At times the clinical symptoms are paroxysmal and explosive, as in the periodical vomiting of children. The chronic as well as the acute food reactions are often due to some particular food toward which the child manifests an instinctive dislike.

The special object of my address is twofold. First, how can we recognize the allergies in their preclinical or developmental stage? Second, what measures can be taken to thwart the development or manifestation of the clinical reaction?

The first of these questions, the early recognition of allergy, or allergic tendencies, brings us at once face to face with the question of pathogenesis. All that we know of this is derived from studies of inheritance. In 1915 with Dr. VanderVeer and in 1924 with Dr. Spain, I collected complete family histories from 796 allergic cases in 549 different families whose total offspring was 1889. The following points briefly summarized were derived from these studies:

FAMILIAL OCCURRENCE

When data were collected from a large number (several hundred) of normal persons, we found an antecedent history of allergy in seven per cent., whereas the 796 allergic cases gave a positive allergic history in antecedents in fifty-eight per cent. This certainly suggests a familial influence.

INFLUENCE OF HEREDITY ON AGE OF ONSET

We divided the allergic cases into, a, those with both paternal and maternal history; b, those with either paternal or maternal history; c, those with no antecedent history.

In the first group (double inheritance) clinical symptoms of allergy began before the tenth year in seventy-five per cent. Where the inheritance was single, only thirty-one per cent. began symptoms before the tenth year of age. Where there was no inheritance evident but twenty per cent. began before the tenth year. These percentages indicate a decided familiar influence on the age of onset of clinical symptoms. The more complete the inheritance, the earlier the age of onset.

AN ESTIMATE OF FREQUENCY IN OFFSPRING OF ALLERGIC ANTEDECENTS

On the basis of these figures it has been possible to estimate that of all children with bilateral allergic

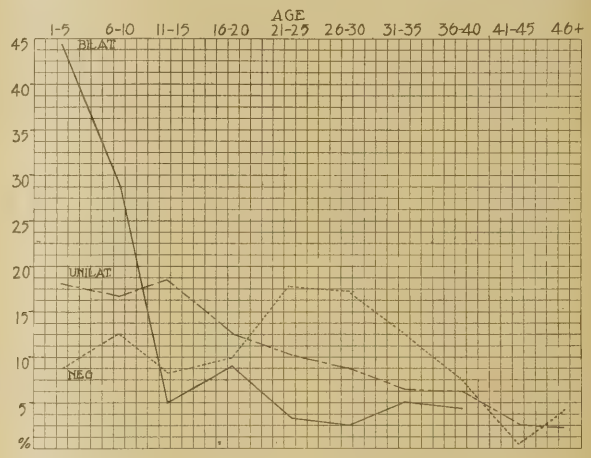

Fig. 1.—Chart showing influence of heredity on age of onset.

inheritance about seventy per cent. will become allergic, while of those with unilateral inheritance about fifty per cent. will become allergic.

I shall not go further in the alluring but speculative field of interpretation on the basis of Mendelian inheritance by dominant recessive or multiple factors, but shall emphasize the point that a positive family history of allergy should arouse suspicion as to the nature of certain disease manifestations in the child.

NATURE OF THE INHERITANCE

One other important point has been elicited in these studies, namely, that the clinical manifestation of allergy in the offspring is as often different from as it is identical with that of the antecedent. For example, the parent may be sensitive to pollen and have hay fever, whereas the child is sensitive to egg, and the slightest contact with it produces vomiting, diarrhea, urticaria and collapse. In other words, the inheritance is not of the condition itself, but rather of a tendency to some allergic state.

MULTIPLE SENSITIVENESS

One other point is of interest in the question of human allergy and that is the fact that in a majority of the cases an individual is or has been allergic to more than one substance. There are persons who are sensitive to as many as twenty-five different substances.

1. An individual may have one clinical condition and be sensitive to many different substances all of which produce this one clinical result.

2. Or, a person may have asthma from pollen, and urticaria and angioneurotic edema from fish.

3. Or, a patient may give a history of egg allergy as an infant which was outgrown at the age of five, and was then replaced by an asthma from dander at the age of eight, and at twenty-five become in addition a victim to seasonal hay fever.

All of which merely shows the curious constitutional defect manifesting itself throughout life. This tendency adds greatly to the difficulty in the management and diagnosis of these cases.

ASTHMA

This is possibly the most important of the recognized allergies because, 1, it tends to a chronic condition which interferes with education, work and pleasure, and 2, the complications and sequelæ are numerous and disabling. The commonest are, emphysema, chronic infection of the bronchial tract, and chronic infection of the paranasal sinuses. The causative factors in asthma vary with the age of onset. When the clinical onset occurs in infancy, it is due to foods or infections. Rarely do air borne substances (pollens or animal danders) cause trouble before the third year. When caused by foods, the attack may be merely a part of an acute allergy with vomiting, diarrhea, erythema, and urticaria; or asthma may occur alone. In these early food cases the development is not gradual. Asthma usually occurs the first time the food is taken, the attack is acute in its onset and it follows almost at once upon the ingestion of the offending food, such as milk, egg, chicken or wheat. These infants are often the victims of severe and protracted eczema. The attacks of asthma in infants caused by infections are limited to infections of the upper respiratory tract and bronchi. They are gradual in their development. Such infants have frequent attacks of bronchitis with an increasing amount of wheezing, until finally a severe attack of dyspnea is associated with the bronchitis; and thereafter each attack is regularly an asthmatic affair, usually paroxysmal, but at times becoming continuous for months, especially in the winter. These infants as a rule have definite lymphoid hyperplasia in the pharynx, tonsils, nasopharynx and lingual tonsils. The hypersensitiveness to foods and infections in infants tends to spontaneous disappearance between the fifth and tenth years, but all too often the asthmatic manifestation continues as the result of a new sensitiveness to inhaled air borne substances.

Asthma that develops from the third to the thirtieth year is usually caused by the air borne substances, pollens, sachets, animal danders, and house dust. Here the onset is gradual. Usually coryzal symptoms begin first. These cases are usually known in the family as "sneezers." They seem to be the victims of frequent mild afebrile colds in the head. Then cough and wheezing develop and eventually an attack of dyspnea stamps the condition as asthma.

Asthma developing after the thirtieth year, and especially after the fortieth, is usually the result of chronic foci of infection in the bronchi, tonsils, teeth, sinuses, etc. Here, too, the development is very gradual. Cough and wheezing and frequent attacks of bronchitis may go on for years before the true dyspnea of asthma begins. Many of the cases of chronic bronchitis with emphysema are truly infective asthmas and should early be recognized as such, for the results obtained with some of these old longstanding cases warrant the belief that much better results could be obtained had they been treated along the same lines that we now follow after they have become definitely asthmatic.

In discussing the measures that may be taken to prevent the development of the allergic conditions, frankly I must admit that I do not know that we can prevent the development of any allergy. When you recall that the whole study of this branch of medicine covers a span of less than fifteen years, you will see that there is good reason for lack of data on such a fundamental question as the prevention of development of an inherited trait. But an early recognition of asthmatic tendencies with a correct diagnosis of the causes will allow a prevention of the clinical manifestations of that hypersensitive condition with its train of evil consequences.

In the infant the only preasthmatic clue lies in the family history. When the reaction occurs to food, it does so abruptly and cannot be avoided, but the condition should be readily recognized and a diagnosis made of the specific cause. The food should be withdrawn from the diet absolutely and for an indefinite time. But when infections occur frequently in the upper respiratory tract and bronchi in infants with an allergic inheritance, attention should be immediately directed toward probably infected adenoids and tonsils. On account of the possible later development of sensitiveness to air borne substances these children should be treated as are older children who are sensitive. Pets should not be allowed in the house. The mattresses and pillows should be of good curled hair and renovated once a year. There should be no box springs on the bed, and only small rugs on the floor, and no overstuffed furniture to hold the dust. In other words the environment should be as dust free as possible. The diet should be simple and emphasis laid upon variety of foods.

Drugs should always be prescribed with care, since asthmatics as a class are often victims of drug idiosyncrasy which is drug allergy. Aspirin and quinine should be used with particular care. Flaxseed and mustard for poultices may do more harm than good. I have seen several children in whom a simple bronchitis has been regularly turned into a violent asthma as soon as the poultice was applied, on account of a sensitiveness to mustard or flaxseed.

CONCLUSIONS

I believe a great deal can be done for the allergic cases by an early recognition of the condition and a prevention of the clinical symptoms. These clues for early diagnosis lie: 1. In the family history. 2. In the past history. Allergies of early life warrant the suspicion of allergy in later life. 3. In the present history a definite allergy should bring under suspicion recurring colds and bronchitis as a possible forerunner of asthma. 4. Finally the physical findings of chronic foci of infection in the respiratory tract should receive attention.

Presurgical Conditions Including Cancer*

EUGENE H. POOL, M.D.
New York

It seems unnecessary and almost presumptuous to tell practitioners of medicine in New York city the things about which I am going to talk. You know them—they have been drilled into you from your medical school days. Yet I shall do it in the remote hope, not that it will add anything to your knowledge, but that it will strengthen your resolutions—resolutions of thoroughness.

The nut which offers the real kernel is the cancer problem. Can you do anything to prevent or limit this affliction? You practitioners are almost the only ones who can. And you have your opportunity through these contemplated periodical examinations. You may ask how? In answer I would say that there are certain conditions which predispose to cancer, the avoidance or correction of which will prevent the development of the disease. Among these may be mentioned senile skin lesions on the face, irritated tongue and gums from rough tooth plates or carious teeth, lip fissures, leucoplacia, and cervical erosions and tears. All of these should be noted and appropriate measures employed to remove the cause and cure the lesion. The danger is that the practitioner will delay in order to determine what will develop. Unless you know definitely that a lesion in the mouth or on the tongue or elsewhere is benign, consult an authority. Under his advice a biopsy, if necessary, can be made. This will settle the question at once. I say, advisedly, get advice before the biopsy, first, because in some cases the necessity for biopsy will thus be avoided; second, the site must be carefully selected; and third, in the case of deep tumors, as of the breast, it is felt that a cancer should not be incised and operation delayed, if operation is indicated.

In regard to biopsies, Ewing states that "the removal of a small carefully selected portion of an accessible tumor seldom results in any harm." And Wood states that experimental evidence indicates that the number of metastases is not increased by biopsy. Nevertheless, even in superficial lesions it is wise to avoid the habit of taking out a piece of tissue in one's office and sending it to a laboratory for an opinion. It is best to allow the consultant or prospective operator to see the case before such interference. And this leads us to several points of vital importance in connection with such laboratory tests.

1. Pick a real pathologist. A technician who makes a slide for examination is not necessarily competent to make a diagnosis. The possession of a microscope does not make a pathologist.

2. The individual pathologist's leaning and general point of view should be known to you. Just as röntgenologists differ in knowledge, accuracy and reliability, so do pathologists. Know whether the pathologist who says "suspicious of cancer, operation indicated," should be blindly followed or his advice checked up.

3. Remember that the pathologist's opinion often can be made much more valuable if he sees the lesion *in situ,* or at least has a thorough clinical record of the case. It is important that the proper site be selected for biopsy, that the tissue removed be gently handled, and not pinched with forceps.

MOST FREQUENT MALIGNANT GROWTHS

I shall now touch upon the more frequent growths and their early recognition.

The person who presents himself or herself for examination should always be considered a potential host for cancer. In women the breast and cervix are the most frequent sites and fortunately a lesion can usually be recognized. They are from a diagnostic viewpoint superficial lesions, as are most carcinomata of the rectum, and the usual excuse for failing to recognize their presence is failure to palpate the breast, inspect the cervix, and introduce a finger in the rectum. While it is assumed that a careful history has been taken in every case, facts suggestive of a lesion may or may not have been elicited. None the less a thorough physical examination should be made and no major orifice should be forgotten. While the question of age has a marked bearing on the incidence of the disease, youth is not altogether immune and the relatively young should be approached by methods of the same thoroughness as those of advanced life. I have known cancer of the rectum to occur at eighteen, and of the cervix at twenty-five years of age. It must be remembered that cancer in the young is usually extremely malignant, hence the importance of early recognition.

Breast.—While a complete physical examination may lead to noteworthy features being recognized on inspection, palpation is the most important factor. The breasts are best examined with the patient lying down, the tissues being palpated with palmar surfaces of the fingers pressed downward against the chest wall. Thus small masses may be appreciated far better than by pinching the tissues between the thumb and fingers as is usually done. A regular, nonadherent, movable rounded mass in a young woman may be assumed to be a fibroadenoma. A rapidly developing painful mass in such a person is likely to be a cyst. And here I must remind you that cancer of the breast grows insidiously and, unfortunately in its early stages, painlessly. The woman with the cyst flies to the doctor on account of the pain; she who harbors a cancer, harbors it with nonchalance for some months because there is no discomfort. These benign tumors and cysts ordinarily indicate conservative surgery. They are removed because, first, there is a possibility, in some, of a mistaken diagnosis, and second, occasionally a benign tumor or cyst later is the tissue in which or from which cancer develops. Small, multiple, rounded, firm areas usually indicate the socalled cystic degeneration (Schimmelbusch disease). In some of these the histological picture is ominous and is described by some pathologists as a precancerous condition. We cannot enter into this discussion nor can one generalize as to the treatment of these cases. The indications in the individual case

*Read as part of a symposium on preclinical signs of disease at the New York Academy of Medicine, January 22, 1925.

must be carefully weighed under proper advice. Bloody discharge usually means a duct papilloma. Such cases demand surgery, as does chronic eczema of the nipple and areola, which is the clinical picture in a type of cancer known as Paget's disease.

We now come to the most vital condition, carcinoma. A hard, irregular mass, however small, must be regarded seriously and immediate action taken. Attachment of the mass to the superficial or deep tissues is of great significance. It must be emphasized that involvement of the skin, shown when the skin is gently pinched between the fingers by pitting or dimpling like pigskin or orange peel, is almost always cancerous. The dimpling may be present over an area of only trifling extent, yet it is significant. Again I insist that such a mass is best palpated with patient lying down. But repeated and unnecessary palpation should be carefully avoided. The importance of this is shown by F. C. Wood. He states that if animal tumors are gently massaged, the number of metastases to the lungs will be greatly increased. The absence of palpable regional lymph nodes should not be taken as an argument against cancer. Do not wait for the appearance of nodes. Their presence modifies the prognosis, but is unimportant from the diagnostic viewpoint. And above all do not try x ray or radium in the early cases. There is no convincing evidence that such irradiation depresses the vitality of cancer cells sufficiently to warrant delay in operation for such therapy; moreover, the contention that irradiation closes the lymphatics of the exposed region has been shown by F. C. Wood to be untenable.

Radical surgery is the only method of treatment in early cases. Into the details of operation I shall not enter, except to state that biopsy should be made in questionable cases at the time of operation, the tumor or breast being removed and a frozen section made immediately. If the report is positive, radical mastectomy is immediately performed. In relatively early cases, where the adjacent lymph nodes are not involved, the prognosis by operation is good. The prognosis becomes progressively and rapidly poorer as the interval lengthens between the recognition of the mass and the operation. I have recently seen two cases in which the women were conscious of having a mass in the breast for four and six months before seeking proper advice. In one, a member of her family, a doctor, favored the delay of six months. In both the delay depreciated enormously the chances of success by operation. In another case a doctor excised a tumor and closed the wound. The pathologist later reported the growth to be carcinoma and the woman was told to submit to a second operation one week after the first.

Uterus.—In many cases of cancer of the uterus a careful history will elicit some suggestive feature. Always regard with suspicion any bleeding between periods, after coitus, after exertion or defecation. Bleeding after the menopause usually means either cancer or polyp (Cragin). Particularly suggestive is a thin watery irritating discharge having a strong odor and occasionally bloodtinged. Loss of weight, and pain are, in general, late symptoms. The cases with suggestive symptoms are not the ones you are ambitious to discover. Therefore, palpate and inspect the cervix in every woman coming for examination unless there are contraindications. And when the speculum is withdrawn do not forget to introduce a finger into the rectum.

In regard to prognosis, in general it may be said that cancer of the body invades adjacent tissues slowly and metastasizes late, while cancer of the cervix invades relatively rapidly and metastasizes earlier. Cancer of the cervix presents either an ulcer, a tumor, or a combination. It is usually hard, granular and bleeds easily. In contrast an erosion or eversion is not an ulceration, and looks bright red and shiny and has a soft velvety feel. Cancer ordinarily appears more grey, and less bright and shiny.

Cancer originating in the cervical canal is the most difficult to diagnose since it gives fewest symptoms and may not become visible at the external os until it is far advanced. In cancer of the body of the uterus, the uterus becomes enlarged, perhaps to a two to three months' pregnancy. The body presents an irregular feel, and is hard and soft in adjacent areas. In the cervix a section may be removed; in the fundus a curettage may be done for examination. But curettage has its limitations and must reach all parts of the wall, and a negative report is not conclusive. Finally, in the absence of cancer, treat and cure the benign lesions. This is of the greatest importance. Cancer of the cervix rarely occurs in a nullipara; it usually develops in the torn cervix which is diseased. Therefore, the correction of erosions or endocervicitis by appropriate methods will do much to diminish the incidence of the disease.

While most other sites are common to both sexes, cancers of the buccal mucosa, stomach, and rectum are more frequent in males. Since the prognosis of even moderately advanced cancers of the tongue, pharynx or cheek is bad under the best of care, the prevention and very early recognition and treatment of these lesions is essential. Prevention embraces the removal and avoidance of continuous irritation and the treatment of benign lesions. The details have been already sufficiently discussed. The results of surgery have been so poor that some authorities favor radium with excision of the regional nodes. While accepting the high percentage of operative failures, these must be attributed in large measure to the rather advanced condition in most of the cases. A cure cannot be expected in these by any measure, and the less mutilating procedure is probably the best. But early cases are best treated by radical surgery, employing radium or x ray as postoperative aids.

Stomach.—Cancer of the stomach may or may not give rise to symptoms early in its course. A history of gastric symptoms suggesting ulcer, especially in one of middle life or advanced age, should lead to a gastric analysis and careful fluoroscopic and x ray examinations.

In the presence of an early cancer, convincing evidence of a gastric lesion can usually be made out. If a lesion is strongly suspected in patients of the cancer age and in reasonably good condition, exploration should in most cases be advised, because early cancers of the stomach, at their usual site near the pylorus, give favorable results by operation if a wide resection is performed. And let me call your attention to the fact that a tumor of large size in the stomach is not necessarily inoperable. In some of these masses the size is largely due to inflammatory reac-

tion with relatively little cancerous infiltration. Moreover, some large papillomatous carcinomata are not extremely malignant and are favorable for operation. The immediate mortality is not high.

The same warning must be sounded here in connection with x ray as was made in regard to the pathologist. Consult a first class man. Money is here well spent. Many plates must often be taken; the fluoroscope should, I believe, always be employed as an aid and check on the plates. This work demands much experience. Therefore, avoid the laboratory where only one or two mediocre plates are made at a nominal cost.

I often have patients come to my office proudly exhibiting a couple of cloudy plates on the basis of which someone had assured the patient that he had or had not a serious lesion of the stomach.

Rectum.—Carcinoma of the rectum is best discovered by chance in the course of a routine examination. When symptoms, such as bleeding, pain, and obstruction have developed, the case is usually hopeless, even if the true condition is recognized as soon as bleeding occurs and is not first treated with suppositories or an operation for hemorrhoids. Whereas the majority of cancers of the rectum can be reached, palpated, and recognized with the finger, many are higher and demand a proctoscope. It is easy to slip in an instrument about six inches and this should be done. I do not think that a routine sigmoidoscopy is necessary since this requires some technical skill and is decidedly uncomfortable.

When a lesion has been palpated or seen, do not delay with attempts, which are often abortive, to secure a piece of tissue for examination, nor to try antisyphilitic treatment. If there is a suspicion of carcinoma, obtain competent advice. Radical operation in early cases gives favorable results, and no other method should be tried in such cases. In the course of routine examinations there seems to be a peculiar forgetfulness of the mucous membrane of the rectum as a possible site of disease, and an aversion on the part of the doctor to making a rectal examination even with a gloved finger. This contention is supported by the fact that in one year I found three cancers of the rectum on routine examinations in cases that had been under treatment with uncertain diagnoses.

Let me illustrate further by citing a recent case. The condition suggested intestinal obstruction. Acute onset, pain in upper left abdomen, and vomiting in a woman of fifty-five, abdomen distended, obstipation. A routine vaginal revealed carcinoma of the cervix infiltrating the left broad ligament. This blocked the ureter and had caused hydronephrosis which gave rise to the symptoms.

Colon.—Cancer of the colon demands a word because it is so often inexcusably overlooked. I recall two cases in recent years of cancer of the colon in which an appendix had been removed and shortly after the operation intensive study of the case, which should have preceded the operation, revealed cancer. Delay and the discomfort of a second operation resulted in each case. Again I recall two cases in which the patients were operated upon, respectively, for gallstones and duodenal ulcer, and these lesions not being found, exploration of the appendix led to the discovery of cancer of cecum. Now all of these would have been recognized before operation, if a thoughtful history had been taken which would have led to a barium enema and plates. The true lesion would then have been evident. Therefore, think of this possibility. Do not lightly advise appendectomy in a chronic case without at least thinking seriously of the possibility of cancer of the colon, and I shall add ureteral stone. The other conditions calling for a differential diagnosis are selfevident. But these two are often forgotten.

Skin.—Skin lesions constitute a frequent and important factor in the etiology of malignant growths. The most common are the flat, scaly or warty elevations on the faces of elderly people, known as seborrheic keratoses. They are the most common cause of the development of basal cell epithelioma. They are treated usually most successfully by radium and can be removed without leaving a blemish.

Pigmented moles and warts have been the subject of much controversy. Many authorities teach that they should be removed, as they occasionally, even without any apparent cause, flare up into a malignant lesion with very rapid melonotic metastases. Some authorities believe that they should not be disturbed until they show evidence of growth or irritation. Whichever viewpoint is accepted, they should be considered as serious possibilities. Those situated in regions subject to constant irritation, as under the belt or collar, should be removed. Such treatment, however, should be undertaken only under expert supervision.

This covers the more common types of cancer. I will not discuss hypernephroma, melanoma, caudoma, lymphosarcoma, and other rare types; nor malignant growths which occur as rarities in certain organs as the thyroid and spleen; nor those which demand the skill of the specialist as prostate, bladder, larynx, and esophagus. In such cases one must be alive to the fact that there is something peculiar and obscure, and if he cannot solve the problem himself expeditiously, immediate advice should be sought.

The possibility of syphilis is often considered when a mass is found and a positive Wassermann reaction is often considered as demonstrating that the mass is syphilitic. Such a conclusion is far from true; a positive Wassermann is no more than presumptive evidence in favor of the diagnosis. It is not conclusive. If a positive reaction is reported, one concludes that the patient is a syphilitic, but the lesion nevertheless may be a cancer in a syphilitic patient. The mistake has often occurred, especially in the rectum and tongue where syphilis and cancer are both relatively frequent. The confusion has even occurred in lesions of the stomach. The practical point is that if there is any question of cancer, especially in tongue or rectum, the diagnosis should not be settled by therapeutic measures. The diagnosis must be made independently of antisyphilitic treatment, and not by noting the results of such treatment.

Cancer has involved so much discussion that I can scarcely touch on other presurgical conditions.

I might dwell upon the recognition of hyperthyroidism by estimation of basal metabolism; the differential diagnosis of high fixation of the duodenum for which the appendix is usually removed as a preliminary operation; and even varicose veins as a precursor of distressing symptoms; but each of these

and similar subjects would require a degree of elaboration which precludes discussion at this time. But all that I could say is covered by the advice that in every case make a complete and thoughtful examination. The type of person under observation should be estimated in all details. Valuable prophylactic advice may often be given the patient who is recognized as belonging to the status type; and one's advice as to operative treatment is often modified by trifling details which are picked up on careful scrutiny and when welded together form a definite index as to what is best for the patient.

Periodical Health Examinations from Viewpoint of Endocrinology*

WALTER TIMME, M.D.
New York.

The glands of internal secretion are subject to the same diseases that attack other tissues of the body. For instance, the thyroid gland is subject to a certain spirochetal infection which we see in South America, known as Chagas's disease; the pituitary body is prone to be attacked by syphilis; and the adrenal glands are attacked by tuberculosis, scarlet fever, and diphtheria. These diseases show affinity for these glands, and as a result we have certain abnormalities resulting from those infections. I am not going to discuss those things. What I intend to discuss is this: The internal glandular system as a system that has to do with constitutional development rather than with disease.

Either an excess or a deficiency of the secretions of the internal glands may have a profound effect on the general health of the body and farreaching results on vigor, immunity, and susceptibility to disease. A physician making a periodical health examination must be prepared to recognize and interpret the more gross abnormalities of the ductless glands.

Over an experience of some years I have found that what we have dubbed overactivity or underactivity of the various glands can probably, in sixty per cent. of cases, be traced back to early periods in our patient's life, even to his ancestry. So we have come to regard a great many of these constitutional disabilities as actually being transmitted through the chromosomes, through families, generation after generation, in not always the type in which they originally appeared, but in various metamorphosed forms. The various types may succeed one another without apparent rhyme or reason.

If one wishes to analyze the situation from the beginning of the patient's own life (which is the only practical way of proceeding), this sixty per cent. of all cases that we see go back to one original type which in its developmental stages produces manifestations in every field of medicine and surgery, and involves every tissue of the body. And this type is the socalled status hypoplasticus. If what I say is true, then status hypoplasticus will repay an intensive study, for it is the recognition of this state early in life which will allow you to prognose, within limits, what is going to develop from that state, what may be expected, what can be helped, and what must be endured. Status hypoplasticus is a term which is probably better in its application than the old term, status thymicolymphaticus, for the reason that the thymus gland is not necessarily a part of it; but the thymus usually is enlarged and plays a collateral not a major part in the production of symptoms.

What is a hypoplastic constitution? It is one in which important tissues of the body are underdeveloped, small and inadequate. Those important structures that are inadequate are, in the first place, the cardiovascular system; in the second place, the series of glands—pituitary, thyroid, adrenals and gonads; and in contrast to these hypoplastic organs, we have the hyperplastic or enlarged ones, those composed of lymphoid tissue, such as the thymus, the tonsils, the lymph nodes throughout the body, the spleen and the liver.

A person that has this constitution presents then, not only these grosser aspects of enlargement or deficiency in size; but in every field, clinical and laboratory, certain minutiæ of the condition are found that influence profoundly his capacity for later survival, reproduction, and resistance to disease.

The blood picture of such a person shows no anemia; the red cell count and the hemoglobin are both normal. But in the white cells you will notice a low polymorphonuclear and a high lymphocyte count, a long coagulation time of the blood, a low blood sugar, and a low alkaline reserve.

Let us interpret these findings. In the first place, take the low polymorphonuclear count which these individuals present; they are frequently victims of infection. Some infective processes with pus formation produce in the regular cases a laboratory picture of blood that is quite significant—that is, there is a high polymorphonuclear count in the number of white cells, frequently reaching ninety per cent. and over. These status cases do not show that high polymorphonuclear count. Their count under an infection process goes up to sixty or sixty-five per cent., and then when it comes to a matter of operative procedure on the basis of the differential white cell count, you are at a loss. That happens frequently. If you recognize that a status condition is being dealt with, you can't place dependence on the differential value at all. That is the importance attached to the abnormal polymorphonuclear count in status cases.

The next important point is that the blood sugar content is down to seventy or seventy-five mg. per one hundred c. c. Now muscular activity depends upon the percentage of blood sugar that is carried to the muscles in question. If this is low, fatigue supervenes rapidly.

Further, note the long coagulation time of the blood—ten, twelve, fifteen or twenty minutes. This long coagulation time is probably, as Cannon and

*Read as part of a symposium on preclinical signs of disease at the New York Academy of Medicine, January 22, 1925.

others of his school believe, indicative of the fact that the adrenal glands are deficient in function, for adrenalin will increase the coagulation power and diminish the coagulation time.

The symptoms dependent on long coagulation time are those of bleeding and purpura, particularly purpura. Part of that problem, though not the entire problem, is that of a long coagulation time. This becomes of great interest in some of the smaller injuries, for they may readily lead to secondary hemorrhages of the brain and other important structures.

Then comes the low alkaline reserve that these patients have. The tendency to acidosis is constantly present. They suffer with periodical conditions of acidosis, with sudden rises of temperature and gastrointestinal symptoms. Thus from this blood picture alone you can see what difficulties these patients have when they undertake to perform their tasks.

Studying their structure we see likewise a condition in which disabling situations arise. Their skeletal units are inadequately bound to one another and to the trunk, and so flaillike joints are produced. They have subluxations of the jaw, of the elbow, of the shoulder—the shoulder particularly. What is still more important is this: that those joints which normally should be fairly well fixed, such as the arch of the foot and the sacroiliacs, are not firmly fixed, and as a result what happens? You have a potentiality for backache which nothing relieves excepting substitution of a better ligament, namely, a strap or belt of some kind. These patients suffer from flatfoot because the arch instead of being supported, is not supported, the ligaments being loose. These conditions handicap these individuals.

Now, without dilating further upon their inadequacies, what becomes of these persons? Many of them die young, before their condition has been diagnosed at all. They die because of sudden fright; because of a sudden drawing upon their deficient adrenal glands; because of some slight infection or narcosis, such as a slight whiff of chloroform. They will have a hemorrhage of the brain or of the suprarenals, and death supervenes without any premonitory symptoms at all. Although they probably had been examined, nothing was found because nothing was known about what should be looked for in their constitutions to make of them inadequate individuals.

Those who do not die survive by what means? There is a mechanism within them, a compensatory group of structures which specifically overcome a great many of their inadequacies. For instance, if the pituitary could enlarge, there would be an increase in the blood sugar; if the thyroid and adrenals could enlarge, there would be more rapid mobilization of sugar and shorter coagulation time. In other words, there is in these patients a mechanism which if called upon automatically will overcome for that individual many of his disabling characteristics.

Now we have a great deal of evidence to show that this is exactly what happens in bringing them out of status hypoplasticus into a more normal condition.

Suppose this mechanism has been brought automatically to begin its work. It will proceed for a certain length of time—for some persons up to the point of normality; but for others only partial success will result, and so many variations will result from early death to mature normality. There are innumerable grades therefore beyond which that process is not efficient. Those patients that represent those innumerable grades from early death to mature normality are the ones you see constantly. What you must know is how far they have progressed in this compensatory process.

Let us assume that after all three of these organs, pituitary, thyroid, and adrenal glands, have proceeded on this compensation course for a period of four or five years, one of them begins to let up in its function, and has reached the point where demands are made upon it for some other specific bodily function. It then becomes for that patient relatively deficient. When puberty arrives, for instance, the pituitary gland is called on for extra work. It then becomes inadequate. We have signs of relative hypopituitarism. The patient begins to get lethargic, becomes fat, has less power of concentration, less initiative, and becomes the fat boy or girl you see about you. He becomes inadequate at the age of puberty.

That disease (if it is a disease) did not begin at puberty. It was inherent in that human being at the time of his birth. It became manifest on the arrival of puberty.

On the other hand, suppose the thyroid is called upon for overactivity, as it is by a persistent thymus gland, and puberty arrives; well, the thyroid is already active, and it becomes inefficient on account of this particular increased load it now has to carry. There arise symptoms of relative hypothyroidism, enlargement of the neck, colloid goitre, sluggishness, increase in weight, mental retardation, dryness of the skin, everything that goes with low oxidation. That did not begin at puberty. That began in early infancy or before. We did not recognize its beginnings. If they had been recognized and at that time corrected, there would have been no hypothyroidism at the time of puberty.

Of hypoadrenalism I know little, and hence I cannot tell you the effects produced in these persons when their suprarenal glands are affected because there are no methods of determining that fact so far as I know of, except that the patient presents inordinate fatigue and low blood pressures. But the large proportion of cases of pituitary and thyroid disturbances that we see at puberty or any other critical point of life at which greater load must be carried than normally, present the symptoms before outlined. These do not arise because of the last cause; that last cause is simply the match that set the fire to the magazine. The magazine was laid long before.

Practical use has been made of the facts. Marine in Cleveland dwells on the importance of recognizing that the administration of iodine early in life prevents certain types of goitre. In a similar way we can prevent other things that arise from disturbances of the internal glandular system. But when it comes to a plain overactivity or underactivity of the pituitary, the thyroid, or the adrenal, each disturbance must be treated on its own merits. There is no way that I know of by which you can tell in advance that one person is to be over or underactive in thyroidal or pituitary action excepting when he belongs to the status type.

Hyperthyroidism may be produced without symptoms of neck pressure except that an unsightly mass arises. When it comes to the pituitary

body endeavoring to compensate and enlarge, the matter is quite different. The pituitary body is situated in a skull within a skull. The pituitary fossa is formed by a fibrocartilaginous, bony structure. When the pituitary body endeavors to enlarge, what happens? Pressure is produced within this fossa and headache thereby arises. These headaches come on periodically, every time the patients overexert themselves, every time they go without a meal for a few hours, every time they are particularly fatigued, and every time they concentrate on some particular problem. Women have them before the menstrual period.

The condition can be detected if you examine the skulls with the x ray. It can be told with certainty what type of person is going to have these headaches, and we do not stop at the foretelling, but we can take measures in advance to diminish their number and intensity. These headaches often last for decades, and then gradually disappear without treatment at all. What happens is that the pituitary enlarges its fossa because it presses on the bony capsule and makes that cavity large enough to accommodate the pituitary at all times and then the headaches cease.

This is not fiction. If you watch the skulls of these patients and take serial pictures, you will find that enlargement of the pituitary does take place. Because the gland happens to be near the nerves that go to the eyes, there may be eye disturbances, such as double vision, or a ptosis; and so it is often believed these headaches are due to eye strain. Some are, but the large majority are due to just this particular process of pituitary pressure. So you see that a great many (and I have only touched upon a few of the important ones) of the endocrinopathies occurring in our practice are attributable to these early symptoms and compensatory factors of status hypoplasticus.

The Skin and Syphilis*

HOWARD FOX, M.D.
New York

There are practically no preclinical signs in the vast majority of skin diseases. They appear as a rule without warning from either the clinical or the laboratory viewpoint.

Two symptoms might, however, be mentioned which occasionally precede the outbreak of cutaneous lesions, namely, pain and itching. Strictly speaking, even these are not preclinical. Herpes zoster in a certain proportion of cases may be preceded by neuralgic pain before the appearance of the characteristic vesicles or even the slightest amount of redness. Itching or a sensation of burning may accompany a number of inflammatory diseases, but is rarely present before the outbreak of the eruption. In the disease known as pruritus with lichenification (lichen simplex) the lesions may be preceded for a variable time by severe itching. Pruritus may of course be present without ever producing any visible evidences of scratching and constitute a disease—*sui generis*.

In presenting the dermatological aspect of periodical health examinations I should like to touch upon three phases of the subject which seem to be pertinent.

1. The significance of the socalled precancerous dermatoses and of scars.
2. Some of the serious diseases whose early recognition is all important.
3. The relation of certain diseases of the skin to internal disorders, often of a more serious nature.

A large number of cutaneous affections have been incriminated as a possible source of malignancy. In this category belong the pigmented nevi, concerning the importance of which opinions seem to differ. There can be no doubt that when a malignant process begins in a pigmented mole (generally a melanocarcinoma) it is most serious. When metastases have occurred, there is no disease which is more certainly fatal. Fortunately it is a rare one. When the almost universal occurrence of small pigmented moles is considered, the chances of malignancy arising from such lesions is exceedingly small. The type of pigmented mole which is most dangerous is the flat, bluish black one. The vast majority of pigmented nevi can safely be left alone. When in rare instances they show signs of activity, they should receive immediate attention and be vigorously destroyed (cautery, electrocoagulation, etc.). When pigmented moles are situated in locations such as the bearded region where they are prone to frequent traumatism, they should be destroyed.

Among other cutaneous lesions which may be the starting point of malignant disease should be mentioned xeroderma pigmentosum, chronic radiodermatitis, senile, seborrhoic and arsenical keratoses, leucoplakia, ulcers, scars, fistulæ, lupus vulgaris, inveterate psoriasis, Paget's disease of the nipple, and Bowen's precancerous dermatosis. While any one of the above mentioned affections may serve as the origin of cancer, this is certainly not the ordinary sequence in the vast majority of cases.

The disease which best merits the appellation of precancerous is probably xeroderma pigmentosum. This appears first in childhood, chiefly on the exposed parts of the body, and bears a close resemblance to the changes produced by excessive irradiation from the röntgen ray or radium. It appears to be a form of sensitization to actinic rays and is eventually fatal as a rule from the formation of prickle cell epithelioma. The termination of severe cases of chronic radiodermatitis is well known even by the laity. Leucoplakia is by no means an invariable forerunner of cancer especially where smoking and other forms of irritation are avoided and un-

*Read at the New York Academy of Medicine, on January 15, 1925, as part of a symposium on preclinical signs of disease with special reference to the management of the health examination, held under the auspices of the Medical Society of the County of New York, Committee on Periodic Health Examination.

skillful or half way methods of treatment are not employed. While cancer may develop upon a lupus vulgaris, for instance, this does not happen except on rare occasions. The same may be said of the majority of the socalled precancerous affections.

Scars of various types will be noted in the course of periodical examinations, though their significance is not always understood. The socalled spontaneous keloid is often seen upon the chest and is a well known racial peculiarity of the negro. It differs from the hypertrophic scar, which does not extend beyond the confines of the original injury. The scars of burns and tuberculosis are keloidal, banded, and deforming, in contrast to those of syphilis which are soft, pliable and small in comparison with the amount of ulceration or infiltration which preceded them. The scars of nodular (late) syphilides with their grouping in circles or portions of circles are often as characteristic as the original lesions which caused them. Scars of herpes zoster, variola, acne varioliformis and selfinflicted wounds (malingering) are generally characteristic.

There are certain serious affections of the skin whose early recognition is of the greatest importance. At this time a cure may be obtained, while if allowed to progress this may become impossible. Lupus vulgaris when appearing at the outset as a small group of apple jelly nodules upon the cheek, especially in young persons, can be excised or vigorously treated by other means. When the disease has progressed, a cure is often hopeless.

Leprosy is a disease which should be recognized early, not only for the sake of others (in communities where the disease is endemic), but for the patient's sake. Even with the modern method of using ethyl esters of chaulmoogra oil, very few lepers, in my opinion, are ever cured. In the earliest stages, however, such an event is possible. Any yellowish brown macules which are more or less definitely anesthetic, especially in persons from a leprous region, should arouse the suspicion of leprosy.

Cutaneous cancer occurs most frequently on the face where it is of the relatively benign type, which practically never metastasizes. On the extremities and genitals and about the orifices it is often a much more serious problem. While cancer of the skin may assume many forms, the most characteristic symptom is the presence of a semitranslucent waxy border. Absence of pain and a tendency to bleed easily are also noted in this disease.

Various eruptions of the skin are simply signs of internal disorders or constitute a single symptom of a general disease. Rosacea is almost invariably a sign of gastrointestinal disturbance, and the same is true of acute urticaria. Lupus erythematosus is probably due to focal sepsis, in some cases of a tuberculous nature. Eczema, furunculosis, pigmentation, and xanthoma may all be caused by diabetes. In rare instances keratoses of the feet may be due to gonoccocal infection. The rare condition known as acanthosis nigricans is an indication of internal malignancy. The dermatitis of pellagra is simply one of the symptoms of a serious disease.

While certain skin diseases are purely local conditions, others should be looked upon as danger signs suggesting a more serious underlying condition.

Syphilis is of great importance because of its well known power of imitating other forms of disease and from the fact that it may involve any of the tissues of the body. That the physician who makes a periodical health examination should be able to recognize all of the manifestations which this disease may produce, is asking an impossibility. No single individual possesses such a vast store of clinical knowledge. The early lesions of the skin and mucous membranes, which are familiar to many, are of little importance compared with the later ravages of the disease. The seriousness of syphilis lies in its late effects upon the central nervous and cardiovascular systems, and the viscera.

In making a diagnosis of syphilis too much reliance is likely to be placed upon the history, which, in the case of women especially, is notably unreliable. High social standing and eminent respectability do not preclude the possibility of this disease. Even with a positive history of a previous syphilitic infection, the possibility of a reinfection must not be forgotten. While rare, it is true, reports of such cases have increased in number since the introduction of modern methods of treatment.

The tendency to place undue emphasis on the Wassermann test is unwise. It should be given due consideration but not relied upon to the exclusion of clinical evidence. If leprosy can be eliminated, a strongly positive test indicates syphilis. A negative test, however, by no means excludes a syphilitic infection, as is frequently shown in the case of typical gummas of the skin. Examination of the spinal fluid may show a positive Wassermann test in cases where the blood examination is negative. Even the spinal examination may be negative.

In the diagnosis of syphilis nothing is of greater importance than the earliest possible recognition of the initial lesion. If every genital sore were regarded with suspicion and dark field examinations made of even the most innocent looking ulcerations, many of the later consequences of syphilis might be avoided. The early demonstration of the Spirocheta pallida in genital ulcers or in neighboring lymphatic glands, makes it possible to gain valuable time by the immediate institution of modern intensive treatment. The habit of cauterizing all such lesions and awaiting developments borders on malpractice.

In syphilis of the nervous system the symptoms will depend upon whether the meninges or the central axis is involved. In the former case there are signs of cerebral or spinal meningitis and in the latter, encephalitis, myelitis or general paresis. While involvement of the central nervous system may occur early in the disease, symptoms are generally not apparent until a considerable time has elapsed. Involvement of the cardiovascular system may give rise to aortitis, aneurysm, myocarditis, aortic insufficiency and angina pectoris. Any one of the viscera may be affected, including the lungs, liver, spleen, pancreas, stomach, intestines, kidneys and adrenals. Many of these visceral conditions are relatively uncommon and their symptomatology obscure. Frequently the diagnosis rests on the serological examination or therapeutic test. That the bones, joints, muscles, tendons, bursæ, etc., may be involved, shows the importance of keeping syphilis in mind in a periodical health examination.

Historical Medicine

Teeth in Olden Times*

THE HONORABLE WILLIAM RENWICK RIDDELL, LL.D.
Toronto, Canada

Within historical times there never has been a period in which the teeth have not been an object of care and an occasion of pride.

Artificial teeth have been found in Egyptian mummies—the lady of King Tut's time and country had her beautiful store teeth as well as her lipstick and perfumery quite on a par with our modern flapper—indeed the only thing in which the modern Canadian can crow over her ancient Egyptian sister is in her bobbed hair. The hard boiled historian of medicine says of these old artificial teeth that they are "an evidence that dentistry and dentists are at all events as old as the coquetry for which Egyptian women were notorious" (1).

In Ancient Greece, we find the *odontogluphon* corresponding to the Latin *dentiscalpium* which the lexicographers solemnly define: *"quo ea quae dentibus inhaerent eximuntur,"* i. e., an instrument by which that which sticks in the teeth is taken out—Anglicé, a toothpick. Then there are *odontotrimma,* a dentifrice or powder for scrubbing the teeth and gums; and *apodontosis,* abstersion of the filth around the teeth. The torture of toothache is not lacking, that was *odontalgia* or the forceps for drawing teeth, *odontagra* or *odontagogon,* called by the Romans, *dentiducum,* a celebrated one being of lead. The man without teeth was *anodous,* or *nodos;* he with white teeth, *argiodous,* or *argiodon;* if his teeth were rough, serrate, etc., he was *karcharadous,* and if he had a jaw with only one tooth, that is, with the teeth grown together he was *monodous,* like the son of Prusias, King of Bithynia, "who had one bone in the place of teeth," says Festus; or Pyrrhus, King of Epirus, "who is said to have had teeth grown together." One with prominent teeth was *proodous* and one who fought with them was *odontomaches.* I do not find any specific name, however, given to dentists: although Herodotus does mention physicians for the teeth.

No one can peruse the long list of compounds of the word *odous* in Greek (2) without appreciating the high regard that marvellous people had for their teeth and the great care they took of them. Cicero, indeed, tells us that the third *Æsculapius* was the first —so they say—to discover toothdrawing (3). But the practice was not approved unless absolutely necessary: three hundred years before Christ the aphorism already had vogue "don't pull, cure": and it was almost a binding rule never to extract teeth unless they were so loose as almost to come out by themselves (4). The celebrated Erasistrates whose most marked characteristic was aversion from bloodletting recommended that forceps should be made of lead so that no tooth should be drawn that was not so loose and wobbly that it could be drawn by lead forceps, that is without any force or violence—one rather wonders what he would have said to the diabolical turnkey which every doctor had half a century ago. Forceps of lead were openly displayed in the Temple of Apollo, the God of Healing (5).

Hippocrates, the father of medicine, advises that in toothache where the tooth is carious and loose, it should be extracted, but if the tooth aches without being carious or loose, it should be burned (6)—this was done by passing a red hot iron lightly and rapidly over the gum. Hippocrates never extracted unless it was absolutely necessary.

When we reach Rome we are on pretty firm ground: it does not seem to be certain when and where artificial teeth were invented: but by the times of Martial (A.D. 43-104) they were certainly in use. The satirist, addressing an old girl, Galla, after gibing her for wearing a wig and using paint, says—"and at night, lay aside your teeth like your silks" (7).

The same satirist indicates that a whole set of teeth made of bone or ivory could be procured. Addressing Fidentinus who aspired to be considered a poet, Martial asks:

"So, Fidentinus, you wish to be considered a poet by means of our verses and hope to be believed? That's the way Aegle seems to herself to have teeth, bone ones bought or of Indian ivory—that's the way the painted Lycoris who is blacker than a falling mulberry seems to herself to be all right—and you by the same logic as that by which you make yourself out a poet, will have long hair when you are bald" (8).

These sets of teeth were bound together by gold wire and in some way attached to the gums (9).

Celsus who lived about the beginning of the Christian era at Rome, and who was an authority in medicine almost to our own times, was of much the same opinion as Hippocrates not to pull a tooth unless it was too wobbly but to burn the gum—he advised to fix the loose teeth and tie them to their neighbors with gold wire (10). Celsus has a good deal about teeth; he advised bursting hollow teeth by peppercorns pressed into them, and seems to have been well acquainted with the results of extraction in cases of ankylosis of the teeth and alveoli, caries and necrosis; his plan was to shake the tooth loose, most painfully, before applying the forceps (11)—not quite our modern local anesthesia.

It would be wearisome even were it possible to trace the progress—generally downward—of the science of the teeth through the Middle Ages—let us make a rest at the fourteenth century.

Much of the knowledge and skill of the Romans was lost but there undoubtedly were dentists—of a sort. So far as can be made out they seem to have been mostly employed in drawing teeth but toward the end of that century we find a remedy for toothache, a gargle with a decoction of sage leaves (12).

*Read before the Academy of Dentistry, Toronto.

François I who came to the throne in 1515 had a dentist (13), so far as I can find the first royal dentist named as such—his Royal Physician Dr. Jean Goeurot paid much attention to the teeth and had a crowd of remedies for toothache which he characterized as the most annoying of all sufferings. He recommended to hold in the mouth camphor water or a decoction of camphor in vinegar, and to put in a carious tooth, a little cotton soaked in the oil of spikenard, to gargle with a decoction of camomile, mint and rue in hot wine.

For cleaning the teeth, the base of all the preparations was deers' horn.

About the same time Erasmus in his *Civilité* published in 1530 tells us that many different powders were used for that purpose; some rubbed the teeth with salt and alum and "many persons had the strange custom of cleaning the teeth with their own urine" (14). Laurent Joubert, Royal Physician to Henry III, preferred to this, wine diluted with water: and most will agree with him (15).

The cures for toothache were endless. Brantôme tells us that the Queen of Spain had sent him when he had the toothache, "a very singular herb—when he took it and held it in the hollow of his hand, the pain suddenly ceased" (16)—the same phenomenon has been known to appear in modern times on approaching a dentist's office or on the exhibition of forceps by the dentist. The marvellous herb was the dictamnus. Another used cotton soaked in oil, others pepper, cloves, sage, spikenard, poppy, mandrake, hyoscyamus—some applied to the temple a plaster of gum elemi (a stimulant gum obtained from various kinds of trees) with a little powder of cantharides: "It's a marvellous thing, the effect of this remedy," says the enthusiastic writer. Some advised bleeding: the celebrated Guy Patin writing June, 1661, says: "I had a severe toothache yesterday which compelled me to have myself bled on that side: the pain instantly ceased as by a kind of enchantment. I slept all night: this morning the pain returned a little: I had myself bled on the other arm and was immediately cured" (17)—which looks like neuralgia.

Tobacco or snuff was also "a marvellous" remedy to relieve toothache.

As to caries, in addition to the excrements, fluid and solid, of the wild cat ("approved by two of the Regents of the Faculty of Medicine" in Paris (18)) there was used a vegetable essence whose composition is alas! concealed from us.

A certain Sieur Rebel in 1540 brought from Egypt "a water which destroyed toothache on the spot—it takes one by the nose and makes one weep abundant tears"—but a phial of four doses cost a louis d'or (19). As a louis d'or was worth intrinsically about four dollars and sixty cents, equivalent to some seventy dollars at the present time, it will be seen that the remedy was rather dear—but who with the toothache and the money would hesitate?

In the country we are told that a very favorite remedy was to rub the tooth with the tooth of a dead man (20).

Local anesthesia is not a new discovery. Writing in 1610, de Courval (21) tells us how a certain charlatan tooth drawer proceeded—he used no instrument but his two fingers, the thumb and the index finger, "before drawing the tooth which the patient wished removed he touched it with his two fingers on the point of one of which he, talking all the time, placed a little narcotic or stupefying powder, so as to put the part to sleep and make it insensible and without feeling. And on the other finger he put a powder marvellously caustic, which had so rapid an operation that in the very moment he made a cut or opening in the gum, it displaced and uprooted the tooth so that as soon as he touched it with his two fingers only he extracted it and sometimes it fell out without being touched." What these powders were we are not told; but the author assures us that it was impossible for any pain to appear "by reason of the said narcotic powder which was placed there at the same time as the caustic, the one on one side of the gum and the other on the other"—*Credat Judaeus Apella.*

However, the author informs us: "It is an assured fact as I have heard said by persons of standing and trustworthy, that most of those whose teeth were drawn by this charlatan afterwards fell into great fluxions and catarrhs by reason of the attractions which had been excited in these parts by the said violent powders: And with some all the teeth fell out, so that having determined to have only one or two drawn, they were thunderstruck to find that they lost nearly all—a thing miserable and deplorable!"

Now, that man was a quack: but the regulars were not without their anesthetic—here is the formula:

Take two ounces of red roses, boil them for a day and a night in strong vinegar: then dry them: take enough and put on the tooth and it will fall out (22).

Here is another: Boil and then reduce to a cinder, earthworms: fill the hollow tooth with that powder and close it with wax. It will fall out (23).

I have spoken of regulars—for there were regular dentists. The profession of surgeons, indeed, were advised not to draw teeth, especially those who used the lancet frequently. The celebrated Peter Dionis (24), Surgeon-in-Ordinary to Maria Teresa, Queen of France, in his work on Surgery says of tooth pulling: "That operation consists only in the effort the wrist must make to pull the tooth: the effect is redoubled when the tooth resists and the operator does not loose hold till the tooth is extracted. That is why the surgeons who have much bleeding practice and who wish to keep the hand light and firm, should never draw teeth for fear that the exertions they must make should render the hand trembling: that work is to be left to operators who perform it daily and who have no other way of making a living"—which may be considered a blow beneath the belt for the primitive exodontist.

The learned author gives another reason: "If I advise the surgeon to abandon that operation, it is not solely by reason of the injurious effect on the hand, but also that seems to me to partake a little of the charlatan and mountebank. In fact most of these extractors abuse their ability in order to deceive the public, making believe that they need only their fingers or the point of a sword to extract the most firmly rooted teeth. But a surgeon should never recognize these tricks of dexterity: and as probity should be the rule in every action, he should keep himself aloof from those who wish to impose on others."

This indicates what the fact was, that many extractors were quacks rather than surgeons; they be-

came so notorious for lying that there was a proverb: "Lies like a toothdrawer."

The Pont-Neuf seems to have been one of their favorite stations: but they were seen at every fair. One of the most celebrated tooth drawer was Jean Thomas, generally called Grand-Thomas: he had, indeed, studied surgery and been admitted Master and he practised with the license of the faculty. He was tall and stout, had the voice of a stentor, bore a red coat trimmed with gold and a *bicorne* or two cornered hat adorned with peacock feathers. He has an enormous sword at his belt and was recognized from afar by his gigantic height and voluminous clothes: he stood on a steel car with four wheels and roared so loud that both sides of the Seine resounded. He had medicine for several diseases (25) but shone chiefly as an extractor of teeth. His star reached its zenith of glory in 1729 when the Queen of Louis Quinze, Marie Leszezynska, daughter of the exiled King of Poland, gave birth to a Dauphin (26). He announced amid the general rejoicing that for fifteen days he would draw the teeth of every one presenting himself and that on Monday, September 19th, he would give a grand open air banquet on the Point-Neuf—the police cruelly stopped the banquet.

Although Dionis advised surgeons not to draw teeth, he did it himself sometimes; and this is how he set about it: "You make the patient whose tooth is to be extracted, sit upon the ground on a cushion (*carreau*); the operator places himself behind him and having caught his head between the two thighs he raises it a little. The mouth of the patient being open, he takes note of the defective tooth so as not to take hold of one instead of the other; then after laying it bare, he separates the gum from that tooth which he then seizes with the instrument which seems to him most suitable. . . . When there is no failure, the patient spits out the tooth with the blood from the gum."

Dentistry made great strides in the eighteenth century: the kings, queens, princes, and princesses with many of the nobility had their own dentists, generally men of talent and education, who were determined rather to save teeth than extract them. There were women dentists; but in 1755 women were forbidden the profession although at that time Paris had only about thirty dentists in all. In 1768 regulations were made for admission as an expert in the care of teeth.

(*To be continued*)

Contributors to the Science of Medicine

Claude Bernard

Claude Bernard, a contemporary of Pasteur, almost rivalled that great man in the discoveries he made which changed, to a great extent, long held views of physiology. He discovered glycogen and the working of the vasomotor system.

Before giving a short account of the results of his researches, however, it will be in place to run over briefly the history of his early and young life. He was born in 1813 in the little village of Saint Julien in the Rhone valley district not far from the town of Villefranche and not very distant from the city of Lyons. This is a wine growing region where his father owned a small estate planted chiefly with vines. This little property came eventually into Bernard's hands and in his later years he used the paternal cottage as a summer residence during the vacations. In this out of the world spot Claude Bernard was brought up in a homely way, as his parents were quite poor and received his education at the Jesuit School in Villefranche. When he had absorbed all the learning taught at this school he went to Lyons, with the idea of completing his studies and obtaining the baccalauréat. However, he stayed there but a short time and began the battle of life. He took a situation with a pharmacist at Lyons where he remained for two years or so. Some of the methods of business practised by the proprietor of this shop so disgusted Bernard that he forthwith relinquished his ambition to become a pharmacist and turned to dramatic art. He wrote a vaudeville comedy which was accepted and had a fair success on the boards. He then set himself to the serious work of writing a historic piece of a lengthy character and with this in his pocket determined to seek his fortune in Paris. Two students as poor and ambitious as himself went to Paris at the same time arranging to meet him there. They met quite by chance some time after in the Place du Panthéon, in front of the well known inscription *Aux grands Hommes la Patrie reconnaissante?* And while the omen did not hold so good for the other two as for Bernard, yet one became a bishop and the other a director of railways. In spite of the fact that in his *Arthur de Bretagne,* his great tragedy, Giradin discovered much promise, he dissuaded him from following a literary career and advised him to study medicine.

Bernard took this advice, and began his career as a medical student under discouraging auspices. He was very poor and eked out the extremely scanty allowance sent by his parents by giving lessons and living in the most frugal manner. Bernard worked with zest at his medical studies, especially devoting himself to anatomy and physiology. He soon made himself a master of what physiology was known at the time. The entire subject was in a state of vagueness and obscurity. For some time, however, he attracted little attention. To the professors he appeared somewhat idle and inattentive, although really he was analyzing and dissecting their lectures and soon found flaws in their reasoning.

In the fifth year of his studies his opportunity came. He was appointed in 1839 intern at the Hotel Dieu and was allotted to Majendie, the leading physiologist of France and perhaps the foremost of

Europe. Bernard's first contact with Majendie was by no means encouraging. The professor was abrupt in manner and took little notice of his new intern, it is said that he did not even know his name. But the extremely skillful way in which Bernard carried out dissections impressed the master, and one day, soon after Bernard had joined the hospital, Majendie called out suddenly to Bernard busy at a dissection, "I say, you there, I take you as my preparateur at the College de France." Needless to say Bernard jumped at the chance and from then on it was comparatively smooth sailing for him. Bernard's career as a physiologist may be said to date from that time, 1841. It may he noted that physiological science was then at a low ebb.

In 1843 Bernard published his first communication which he followed in December of the same year by his *Thèse pour le Doctorat en médecine,* having for title *Du suc gastrique et son rôle dans la nutrition.* This showed the trend of the investigations of the man who afterwards was known as the father of endocrinology. This paper led the way to the discovery of the glycogenic function of the liver and is further interesting as containing the record of an experiment which has since become classical, that of the simultaneous injection of potassium ferrocyanide and ferrous sulphate, by which is shown that the acid of gastric juice makes its appearance on the surface and not in the depths of the gastric glands.

He next turned his attention to the properties and uses of the pancreas. But it was not until 1856 that he published the complete *Mémoire sur le pancreas et sur le rôle du suc pancreatique.* Up to this time little was known of the part played by the pancreas in intestinal digestion. Indeed the great advance of knowledge in this direction we owe in the main to Bernard. The publication of this memoir brought the young physiological inquirer of Paris into the limelight, not in France only but in all lands in which science was studied. This was but the forerunner of his immortal discovery. As said before, knowledge of the pancreas and of the chemistry of nutrition in general was vague when Bernard took up research work on the physiology of sugar. It may almost be said that he came upon his great discovery by chance, because he found sugar in the hepatic vein when by the knowledge of the time no sugar should have been there. With the genius of the true inquirer, Bernard asked himself why, and proceeded to discover the cause.

After making long investigations he felt justified in making known to the world that the liver is capable of producing sugar, not brought to it as sugar in the food, that sugar makes its appearance in the liver itself by an act which seems very analogous to the act of secretion by a secreting gland, and which therefore might be termed an internal secretion. He followed up these investigations further and finally proved that the liver produces sugar by means of a mechanism analogous to that of secretion at the expense of the elements of the blood traversing the hepatic tissue. He finally isolated glycogen. As a link in the chain of special problems concerned with digestion and nutrition the value of this discovery is inestimable, and as Sir Michael Foster said, "No less pregnant of future discoveries was the idea suggested by this newly found out action of the hepatic tissue, the idea happily formulated by Bernard as "internal secretion."

The study of the internal secretions, while as yet only in their adolescence, has opened already a wonderful vista and we are on the threshold of discoveries which may and probably will alter our conceptions of medicine and its practice. It is thought by many that the key of the riddle of health and disease is in a definite knowledge of the internal secretions and their exact rôle and mode of action. The discovery of insulin was a step in the right direction and it seems that like discoveries and great are in the womb and will in due course be brought forth. The key of this riddle was found and partly turned by Bernard, other investigators have turned it further, till finally when the key has been fully turned the riddle will be made clear to the advancement of the human race physically and mentally.

In commenting on Bernard's work on glycogen, Foster truly says: "It has been the fate of many other men in many matters to have merely laid a foundation on which other men have built. Bernard, in the matter of glycogen, not only laid the very first stone, but left a house so nearly finished that other men have been able to add but little."

Another outstanding discovery made by Bernard was that of the vasomotor system, which in point of importance hardly ranks second to the discovery of glycogen. In this discovery, however, he did not take the leading part nor pursue his first line of investigation so persistently as was the case with glycogen. Others first recognized the importance of his earlier result, the vasomotor function of the cervical sympathetic. He discovered it somewhat accidentally. He was looking for something else, and did not, as he did with glycogen, relinquish the line of inquiry which he had originally laid out for himself, and give himself up to the new line of inquiry. He thought he was "off the track," so to speak, and it was only because of the interest which others manifested in the intercurrent vasomotor phenomena that he was persuaded to continue along this line of investigation. Brown-Séquard, who was living at the time in Philadelphia, interpreted the significance of the phenomena and unhesitatingly completed the vasomotor proof. Later on Bernard, quite independently of and apparently in ignorance of Brown-Séquard's results, himself also supplied the second half of the vasomotor proof.

Bernard made a close study of poisons and made many experiments in this kind of research. With regard to curare he found out some valuable facts. He also analyzed the physiological action of carbonic monoxide gas and discovered the why and wherefore of its extremely poisonous effects. Many other results Bernard arrived at, such as the socalled paralytic secretion, the supposed reflex activity of the sympathetic ganglia and others. One observation of his perhaps deserves notice. In the fifties, biologists, especially in France, were deeply concerned with and discussed with considerable vehemence and with a high degree of acidity, the question of spontaneous generation, a question which Pasteur decided once and for all time. In 1858 Bernard took part in the discussion and showed that the growths which readily appear in a solution containing gelatine and dextrose exposed to the air, do not appear if the

solution be supplied exclusively with air which has passed through a red hot tube. He argued that the growths which usually appear are not spontaneous in origin but have their source in air borne germs, and the red hot tubes killed the germs on their way to the solution. According to Foster much of Pasteur's refutation of the spontaneous generation theory was on the lines of Bernard's experiment.

Nearly all the great achievements of Bernard's career were accomplished before he was fifty years of age, indeed his two greatest discoveries were made before he was forty years old. And in this connection, too, the point may be emphasized that Bernard did his work and solved problems under conditions which are incredible to research workers of the present time. In the first place he had to contend with almost grinding poverty and endure privations of the most severe kind. In addition, his working hours were beset with difficulties. The laboratory in which he worked under Majendie, if it could be called by such a high sounding name, was a dark, unwholesome room in the lower story of a building referred to as a damp and dark lair, the apparatus provided was elementary and wholly inadequate for the purpose and also experimental physiology was eyed askance. The path of the physiological investigator in those days was strewn with thorns. Not for Bernard nor Pasteur, although the research worker in chemistry enjoyed better facilities than the physiologist, was there a well equipped laboratory with adequate apparatus with a master who trains the probers of the mysteries of medical science in technic and suggests and guides the line of work. Neither in Majendie was found such a master, but rather an abrupt and rude man who left his assistant very much to his own devices. As a matter of fact Bernard had to carry on his experimental inquiries in some temporary laboratory of his own, or in that of one of his chemical friends.

Both Bernard and Pasteur made their world famed discoveries in circumstances which would discourage, nay appall, laboratory workers of this day, and yet it is a moot question whether they did not benefit by these hard conditions. They were imbued with a real passion for science and thrown upon their own resources, often invented or even made their apparatus, and lacking the guidance and suggestions of a master evolved from their own inner consciousness together with the insatiable curiosity of the born investigator, their discoveries. They wanted to know why and found out for themselves. And often when they went astray they found out something they were not looking for. It is futile to moralize as to discoveries in science but it sometimes seems that the greatest discoveries made are in proportion to the difficulties met with. The greater the obstacles to overcome the greater the discoveries. Bernard possessed an intuitive perception or was led by a sort of inspiration to anticipate conclusions which it took patient plodding workers months and sometimes years of laborious study to reach. He reached the conclusion leaving the gaps left on the road to the goal to be filled in afterwards either by himself or by some other person.

In 1847 Bernard stepped into Majendie's shoes as deputy of the College of France so that he was provided with better facilities from that time on. His domestic life, unlike that of Pasteur, was not happy.

In 1855, on the death of Majendie, Bernard was made a full professor at the College of France. He worked incessantly during the next few years. While extending and completing his discoveries, at the same time he gave lectures at the College of France and at the Sorbonne and he largely used these lectures as a means of making known new results. These lectures were published eventually under the names of *Leçons de Physiologie Experimentale, Leçons sur les effets des substances toxiques et medicamenteuses, Leçons sur la physiologie et la pathologie du systeme nerveux,* and so on. In all, these lectures form seventeen octavo volumes. In 1862-63 his health broke down. The exact nature of the malady was not diagnosed but it was probably appendicitis. Off and on he suffered from it until 1867 when he had an acute attack and the abscess appears to have discharged into his bowel. He recovered slowly and became strong again. In 1862, when his health seemed to be definitely failing, he betook himself to his native place where he had continued to hold his small ancestral estate. When, however, health and vigor returned country pleasures and occupations began to pall although while in the country he wrote a book entitled *Introduction to the Study of Experimental Medicine.* Bernard was a pioneer in that science which now belatedly appears to be coming to the fore, namely, that of comparative physiology and pathology. Towards the close of his life he was drawn more and more to those fundamental properties of living bodies which may be observed alike in animals and plants. In 1864 or thereabouts the Emperor Napoleon III, who wished to be regarded as a Mæcenas and especially to men of science, invited Bernard to take part in the festivities of Compiègne. Bernard accepted and paid the visit in company with Pasteur. A few days afterwards the Emperor sent one of his ministers to inquire of Bernard what could be done for him. "For myself," said Bernard, "I want nothing; but my science is in great want of proper laboratories." As the result two well equipped laboratories were established, one at the Sorbonne and the other at the Museum d'Histoire Naturelle at the Jardin des Plantes in connection with the chair of Physiologie Generale which was being instituted for him there and into which he entered in 1868. At about that time he was admitted into the Académie Française and in 1869 the Emperor made him a member of the Senate. He lived alone and went very little into society.

Bernard's appearance was in keeping with his great reputation. He was a tall man of noble and dignified presence and his conversation was particularly brilliant. In 1877, the last year of his life, he made three contributions to the Société de Biologie, one on animal heat, the other two on the gastric juice. He also contributed three papers to the Académie des Sciences, all three dealing with the old subject of the glycogenic function of the liver.

When working in his laboratory at the end of the year 1877 he was seized with a chill which ushered in an acute affection of the kidneys and he passed away on February 10, 1878. He was accorded a public funeral and was the first man of science in France to be laid to rest in the Cathedral of Notre Dame. Undoubtedly Bernard was one of the greatest men of science produced by France.

EVOLUTION IN SCHOOL HEALTH WORK

Evolution in school work in this country has gone along after the manner of movement of the crawfish.

It started with the employment of a physician to examine and prescribe for the health of college students. Thence, after a lapse of a half century it descended into the public schools, and now after another quarter century it is being applied at the root of things,—to the child before entrance to school. In school work the physician was, at first, a mere searcher after vermin, the possessors of which were expelled from school. Today he is getting down to fundamentals by determining the condition of the machinery and the nutrition (with all that goes to make nutrition) of the young aspirant for mental enlightenment.

There were very few results from mere medical inspection, for the average parent was not much impressed with a note saying that Johnny was out of fix and something had better be done about it. The school nurse was next brought in, chiefly to treat cases of verminous infection, but also to visit homes of parents who did not respond to the simple note from the principal. She got much better results but with an unnecessary waste of shoeleather and time.

In the present phase it has dawned at last that the parent is more interested in the child than are the school doctor, school nurse and school mistress; also someone was discerning enough to realize that the parent knows more about the past history and habits of the child than anyone else and that these matters are of importance. In England, where parents were first invited to be present at the examination of the child, a large percentage respond. Even in the city of London eighty per cent. of parents are present at the first examination.

The parents not only furnish valuable information regarding the child but they see the examination, come in touch with examiner and teacher and do not need to receive either notes from principals or visits from nurses. They know what it is all about and are glad to fall in with the intentions of the schools.

In the beginning the physician was everything in medical inspection. Only he could detect a decayed tooth, a hard of hearing ear, a badly visioned eye, or a nonfunctioning nose. Only he could know when a child was acutely sick. Later, much of the routine work of examining was reluctantly and fearfully entrusted to the nurse. Recently it has dawned that the teacher who is most familiar with the children and sees them from day to day is really better placed to observe what is wrong with them, at least on the surface, than anyone else. The nurse and physician become clearing officers and advisors, and their time is saved, and public money economized. After three quarters of a century of floundering in the wilderness we are really getting down to the root of things as regards the health of the school child and we are doing things in a sensible fashion.

DIATHERMY AND GONORRHEA

The treatment of gonorrhea is in many respects unsatisfactory. For example, the treatment by irrigation, external applications or vaccines in the case of the joints, the cervix uteri and urethra in the female and the prostate in the man is not altogether encouraging. Diathermy in the treatment of gonococcal infection has been on trial for some time, and many of those who have employed this form of treatment have reported good results. Mr. E. P. Cumberbatch, of St. Bartholomew's Hospital, and Mr. C. A. Robinson, of the West Middlesex Hospital, London, heads of the electrical departments in these hospitals, have written a book on the subject, which has been published recently by William Heinemann, London.

They have had very fair success in the treatment of several conditions due to gonococcal infection, perhaps, especially so in the treatment of gonococcal arthritis, but the most interesting part of the book is that in which the authors discuss why diathermy exerts its beneficial action. It does not seem to be the heat alone for it is doubtful whether they have ever heated the interior of large joints such as the knee to a temperature as high as 113° F. Yet they have been able to obtain cure or arrest of gonococcal arthritis in the knees by applying diathermy to the joints only. Again in the case of the prostate, it is very doubtful if they have ever heated the whole of this gland to a temperature of 113° F., nor have they subjected it to this temperature for as long as thirty-seven minutes on any one occasion. Yet they have been able in cases of gonococcal arthritis to cure or arrest the latter by applying diathermy to the prostate only.

Therefore, they think it is probable that the disappearance of gonococci from the infected tissues and the relief of symptoms are due not wholly to the direct action of the heat on the invading organisms, although it is certain that the heat diminishes the vitality of the gonococci, if it does not kill them. They are of the opinion, however, that the heat must also increase the powers of the tissues to exterminate

the invading organisms. A heated part gains an increased blood supply. Heat also increases the power of the tissues to form antitoxins. Since the heat produced by the diathermy current is actually generated within the tissues and not applied to the surface, it can increase the blood supply through the infected parts. The authors consequently hold, that the therapeutic power of diathermy in gonococcal infection is due to the action of heat not only on the organisms but on the tissues, the action being hostile to the invaders and helpful to the invaded.

In short, it stimulates the natural defenses of the body to fight as vigorously as possible to protect itself. This view of the action or part of the action of diathermy is very interesting and is quite in accord with the most recent views of therapeutic treatment in general. A drug does not attack directly the invading organism and destroy it or lessen its power for evil as was once believed of some of the most powerful drugs, salvarsan, for instance, but stimulates the defensive functions of the body to fight. If they cannot be stimulated to fight successfully, because vital resistance has been too greatly weakened by the virulent or protracted nature of the attack or perhaps by both of these, treatment fails; if otherwise, a cure is effected or at any rate relief given. It seems from the account of treatment by diathermy in the book by Cumberbatch and Robinson, that their experience of such treatment fits in with the most modern ideas as to therapeutic action.

SEMEIOLOGICAL VALUE OF MUCOUS POLYPI OF THE UTERUS

Mucous polypi of the uterus are not to be regarded as benign lesions and to be removed by simple ablation, because in most instances they accompany some other morbid process of the uterus—metritis, fibroma, cancer—and are occasionally the first clinical manifestation of the latter. For that matter this is merely a particular case of a general law of gastric, urinary and otorhinolaryngological pathology, which shows that polypi accompany diseases of the sinuses, inflammatory or malignant, and gastric, intestinal and bladder processes, as well as ureteritis.

The coexistence of mucous polypi and various types of metritis is well known and should lend to the treatment of the latter. On the other hand, it must not be forgotten a mucous polypus may be symptomatic of, and the only objective sign of, uterine cancer, either of the body or isthmus of the uterus.

The frequency of lesions of the uterine mucosa accompanying the growth of fibromata—hyperplastic, congestive or fungous—is common knowledge, so that the coexistence of mucous polypi and uterine fibroma is, *a priori*, not astonishing and clinically the former may be the only objective evidence of the latter process, usually a latent submucous fibroma.

Therefore, in practice submucous uterine polypi offer a great prognostic value which must not be underestimated and when met with a uterine lesion should invariably be suspected and searched for and thus the causal lesion, of which the polypus is only a symptom, can be properly dealt with.

BODY BUILD

There are as wide ranges of metabolic peculiarity in man as is shown between a razorback and a Berkshire pig. Davenport, in his recent study of *Body Build and Inheritance* finds that these peculiarities with their resultant products of slender or heavy types of structure, or of leanness and fatness, are decidedly matters of heredity.

In a time when too much is being made of height weight indices as measures of nutrition, some of his conclusions are of interest as supporting opinion from common observation.

"There is a marked tendency for persons of similar build (or with potentialities for such) to intermarry. Dissimilar builds are selected against. Two slender parents of slender stock have rarely any progeny whose index exceeds 2.2 or just above the upper limit of the slender group. In general, the progeny of slender parents are relatively slightly variable.

The offspring of two fleshy parents are twice as variable as those of slender parents. The hypothesis is indicated that, genetically, build is controlled by multiple factors, with fleshiness tending to dominate slightly over slenderness.

The diseases associated with very slender and slender build are: tuberculosis, pneumonia, nervousness, melancholia. The diseases associated with very fleshy or fleshy build are: diabetes, nephritis, apoplexy, and arteriosclerosis and paralysis accompanying it; also diseases of the alimentary tract.

Davenport gives instances showing that food intake and build often far from correspond, but no one has explained why this is the case.

"Whatever the fundamental cause may be," he concludes, "the fact remains that in certain families there is a widespread inclination to the production of slender individuals, while in fraternities certain proportions (though usually not all) of any fraternity are fleshy or obese." Perhaps the two kinds of individuals do not metabolize their food in the same way. In any case we can not disregard the constitutional factors in build.

"Looking at the matter broadly, we can see that no other theory than that constitutional differences as well as nutritional differences determine build is sufficient to meet all the facts."

PLANS FOR PHYSICIANS' HOME

A national movement, the first of its kind in America, is under way to establish an endowment fund to build a physicians' home where aged, indigent and decrepit physicians may spend their latter days in comfortable and tranquil surroundings, and where younger men who need medical treatment and have not the wherewithal to afford it may receive the best at small cost. The project has received the official sanction and backing of the American Medical Association and of the New York State and County Medical Societies, as well as that of most of the leading physicians of the country, including Dr. Charles H. Mayo, who is head of the Committee of Sponsors in charge of the campaign. Many interested laymen also are contributing.

The physicians' home is by no means a new experiment, for a few years ago one unit was established at Caneadea, N. Y., through the generosity of Dr. Stephen V. Mountain, who donated the property and building. This unit has had so great a success that the directors believe it to be their duty to enlarge the scope of the enterprise because of the large waiting list for the Caneadea Home. The sum necessary to build the home has not as yet been determined, but it must aggregate several millions of dollars in order that the upkeep through interest may be guaranteed, not only of the main national home, but of the smaller units to be established in various states. National headquarters for the campaign have been opened on the twenty-second floor of the Times Building, New York City. Checks should be drawn to the order of the Physicians' Home, Inc., and should be forwarded to Dr. Albert G. Weed, National Treasurer, Times Building.

The general plan of the home provides for the care of a thousand or more physicians at the central home, and a dozen or more at each branch. The funds donated will be invested in bonds of secure and high earning value in order to assure an adequate return in interest for maintaining the home and the units without recurring appeals to the medical profession or others interested. The name Tranquillity has been tentatively chosen for the home as most fitting and suggestive of its projected character. It will be constructed and the grounds laid out so as to typify and provide a real home where all the creature comforts essential to health of body and peace of mind may be found. One feature will be a laboratory where resident physicians may continue investigations and study, thus enabling them to continue their contributions to medical science and at the same time to enjoy pleasant and beneficial occupation of mind and body. Another feature of the home will be provision for the wife and other dependents so that families may remain intact.

At present the plan is to inaugurate the campaign with a banquet in New York City to which the profession generally will be invited, as well as prominent lay men and women interested in the project. Many well known speakers will take part in the campaign. The officers and directors of the Physicians' Home, Inc., are Dr. Robert D. Morris, president; Dr. William H. Dieffenbach, vice-president; Dr. Albert G. Weed, treasurer; Dr. Silas F. Hallock, secretary; Dr. Warren Coleman, Dr. Max Einhorn, Dr. Wolff Freudenthal, and Dr. Ralph Waldo, all of New York; Dr. J. Richard Kelvin, of Brooklyn, and Dr. Stephen V. Mountain, of Olean, N. Y.

The Medical Journal and Record is glad to extend its hearty approval and endorsement of the project for the Physicians' Home, Inc., for no cause could be worthier than that of providing rest and comfort for the medical man who has given his life and energy for the sake of the welfare of humanity.

Obituary.

EDWARD W. WALKER, M.D.

Cincinnati

The death of Dr. Edward W. Walker on October 7th removed a prominent figure from the medical profession, not only in his home, Cincinnati, but from the whole of the Middle West, throughout which section of the country his work was particularly well known.

Dr. Walker had been ill for some time with a general breakdown after his long and useful life of seventy-three years. His specialty was surgery, and his name will always be associated with those of three others of the most noteworthy surgeons of Cincinnati, Dr. C. S. Muscroft, Dr. P. S. Conner, and Dr. N. P. Dandridge, with the last of whom he was instrumental in founding the Children's Hospital of Cincinnati.

Dr. Walker was a graduate of Harvard University, and took his degree in medicine at the Medical College of Ohio, Cincinnati, in 1877. After a brief internship, he went to Europe, where he studied in some of the leading medical institutions. When he returned to Cincinnati in 1886, he was made demonstrator in pathology at Ohio Medical College, and later appointed to the chair of surgery and pathology at Miami Medical College. He served later as a member of the Cincinnati Board of Health, was professor emeritus of clinical surgery at the College of Medicine of the University of Cincinnati, staff physician at the General Hospital, and served several terms as president of the Cincinnati Academy of Medicine. He was also associated with the Ohio State Medical Society, the American Medical Association, and the American Surgical Association. Dr. Walker was also prominent in Masonic circles, and a member of many political and welfare organizations of Cincinnati.

New York Academy of Medicine's New $2,000,000 Citadel of Public Health

JOHN WALKER HARRINGTON
New York

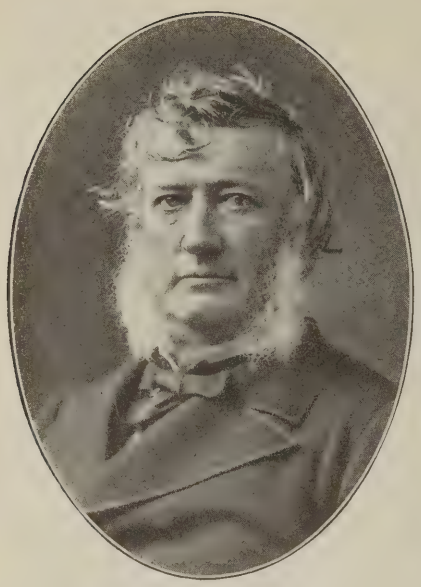
With its library, the second largest of its kind in the country and its historic collections open to the laity, and its ceaseless activities for humanity, the New York Academy of Medicine's new $2,000,000 citadel of the public health, the cornerstone of which was laid last week, will have an unusual appeal, popular as well as professional.

Therapeutics makes good its ancient lineage from the Greek *Therapos,* a servant, in every detail of its plan. When it is finished an appropriate inscription for the door lintel would be that suggested from the motto of a princely crest: "I serve." The structure will be dedicated, in effect, to the American people, for the most of the building fund came from pioneers of two great American industries and many treasures of science and art to be transferred from the present quarters, were donated by men and women outside the medical profession.

It was a small beginning from which grew this institution which has had so wide an influence on the physical well being of the American people. The inhabitants of these United States, when the new New York Academy was born, were accounted a most sickly race. They were so pale or yellowfaced, so thin, and so dyspeptic, that distinguished foreigners grew eloquent over their general debility. As was said of Rufus Choate, the average American had no constitution to speak of and just managed to squeeze through life under the bylaws. James Ford Rhodes in his *History of the United States* referring to the poor condition of the citizens of this land of the free, quotes Harriet Martineau as declaring that here the feeling of vigorous health was almost unknown. Thackeray wrote from New York that "the ladies were as thin as greyhounds," and Dickens, stopping in our eastern metropolis commented upon the hogs which then constituted its street cleaning department and gave patronizing advice about hygiene. Emerson, when in England in 1847, alluded publicly to "the invalid habits" of his fellow countrymen. Pleas of illness were made everywhere, and even when two New Yorkers met, their salutations of "How's your health" were cues for a symptom symphony.

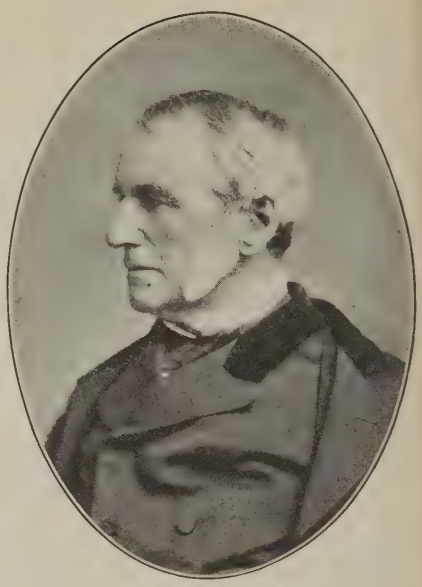
The New York Academy of Medicine was started when the new light of preventive medicine was dawning, and it proved a helpful guide.

There were several small social clubs or coteries among the physicians of New York in the "Fabulous Forties" and most of their members also belonged to the Society for the Relief of the Widows and Orphans of Medical Men, which still exists. There had been an academy of sorts some years before the



FORDYCE BARKER, M.D.

ALFRED LEE LOOMIS, M.D.



WILLARD PARKER, M.D.

organization of the present one was broached, but it had fallen by the wayside. The founding of a new one was discussed at a meeting of the society at the Astor House, then considered the last word in hotel splendor, but the actual founding took place at a fashionable restaurant known as Peletiers, at Broadway and Prince Street, and not far from Niblo's Garden. Eventually the infant Academy was cradled at the Lyceum of Natural History and from there it passed through various cycles on its way from site to site on the island of Manhattan.

From the first it became an advocate of public well being. It started agitations which gave New York City better sewers; founded a Board of Health; insisted on establishing sanitary police; built up the Quarantine service; demanded a pure milk supply and got itself violently disliked by certain interests for insisting that cattle fed on distillery mash were not good producers of baby food. Its successful crusade caused the policing of the Croton Watershed, and constant analyses of the reservoir contents. Committees from the Academy campaigned against high infant mortality and due largely to its efforts, the American Medical Association established a special section to advance the treatment of the diseases of children. It thundered against quackery; drafted a code of medical ethics and so obtained the passage of license laws distinguished between regular and irregular practitioners. Its movement for the more complete isolation of cases of contagious diseases, culminated in the founding of the Willard Parker Hospital. It became a pioneer in the then new science of bacteriology, helped introduce antitoxins for diphtheria; advocated Pasteur's methods of inoculating persons bitten by mad dogs, and promoted the use of sera and vaccines. Forceful, plain spoken leaders of those days have long since been gathered to their fathers, but the old Academy continues to function through its committees on education and public health, and in innumerable ways that make for the common weal.

Its first important headquarters for which it raised a considerable fund, were at 12 West Thirty-first Street, where a highstooped house of the Brown Stone Age was remodeled.

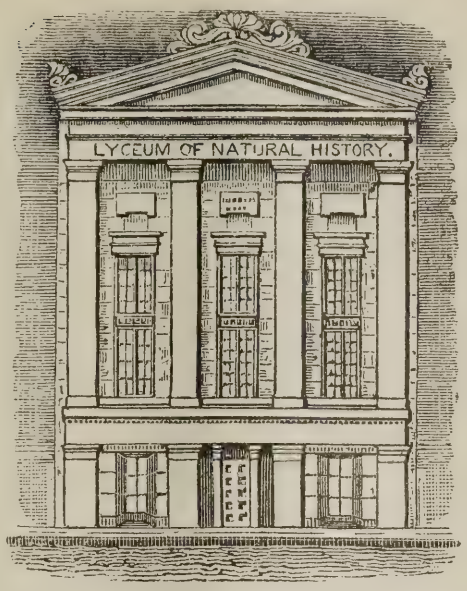
The building at 17 West Forty-third Street, from which the institution will be moving before many months, was opened in 1890, and a splendidly appointed structure it is still, although now totally inadequate for the work done there and for housing the scientific, literary and artistic treasures. It was in this building, in 1897, that the semicentennial was celebrated, the orator of the day being Grover Cleveland, then President of the United States.

Home of the Academy from 1860 to 1875, College of Physicians and Surgeons, Columbia University, Fourth Avenue and Twenty-third Street.

It was proposed, as early as 1909, that a new structure be erected. Some ten building projects and five sites were considered and rejected. In 1922, the Carnegie

Corporation donated $1,550,000 and the Rockefeller Foundation provided an endowment of $1,250,000 for the keeping up of additional educational and library activities to be directed from the new quarters. The sum of $531,384.05 was pledged, of which the members gave about half, and lay friends the balance. What with the three quarters of a million dollars which had been amassed all these years, the Academy is well equipped to enter upon a new phase of its useful service and to utilize additional funds.

The location of the new building at the southeast corner of Fifth Avenue and 103rd Street is within convenient reach of leading hospitals, such as Mt. Sinai, the Fifth Avenue, the Presbyterian and by no means remote from the new medical centre which is to be created at the upper end of Manhattan Island. To the lay sightseer it will be associated with the Metropolitan Museum of Art, the New York Historical Society and various other institutions which loom on the cultural horizon.



First home of the Academy, Lyceum of Natural History, 561 Broadway.

As is the present structure in West Forty-third Street, the new home will be in the Romanesque style in which its architects, the Messrs. York and Sawyer so much excel. The contractors are Marc Eidlitz & Son, Inc., and Mr. Frank Sutton is the consulting engineer. The building will have a frontage of one hundred feet on Fifth Avenue and a length of 175 feet in the side street. The main part will be six stories high, exclusive of the mezzanine which really makes it seven, and the roof will be one hundred feet above the curb. The lower part, or wing, will be fifty feet high. The walls are to be of creamy limestone and red sand stone combined, and will have that varied tapestry texture which is always such a delight to the eyes.

Beginning now from the bed rock, there will be a sub-basement stored with fuel and oil and all manner of gear for heating and lighting and artificial ventilation. There will be receiving and packing rooms for the huge library, wash rooms and all kinds of utilities—accessible by lifts and elevators. The basement is to have a large work room for the mechanical staff, lavatories, storerooms and also a very complete kitchen in which a banquet could be cooked for hundreds of persons.

We come now to the first or ground floor, which will be reached from a wide arched entrance on the side of the building, an arrangement made necessary on account of the pressure of traffic in Fifth Avenue. The entrance will give into a commodious hall or foyer forty-five feet in length and twenty-two in width. Immediately at the right will be a reception room; next to that, a large pantry and last, a combination exhibition and collation room.

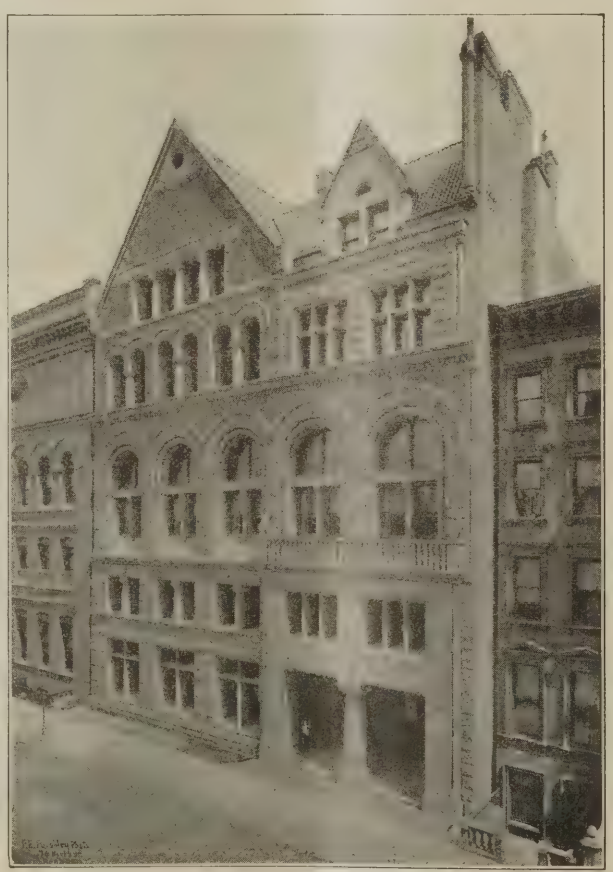
Ever since that memorable night at Peletier's, more than three quarters of a century ago, the New York Academy of Medicine has not neglected the inner man. After every meeting, when it had quarters of its own, a repast was served. Some years ago there was a jovial soul, Dr. Alfred Lee Loomis, by name, who had charge of these refreshment proceedings. He contributed to the expenses himself and designated Mr. John S. Brownne, the librarian, to collect the balance. When the good doctor passed from these scenes, it was found that he had left a bequest of $10,000 as "entertainment fund" with the income of which the Academicians were to refresh themselves. In the Forty-third Street building there is a room, most ornately furnished, paneled, and having a ponderous French overmantel, in which the Loomis collation was served after stated meeting. Of course, no papers of New York physicians can be dry, but if they were, the good cheer furnished by the will of that prince of good fellows, would have proven the effective antidote. Before the pre-Volstead era, in those dear damp days beyond recall, a punch was a prodigious impetus. It glowed in a silver bowl, kegs of cool beer gave their cooling amber rills, and salads and tempting sandwiches and ice cream in alluring forms comforted and stayed the soul. Of course, even before the spectre of the Cost of Living stalked, the fare had to be extended somewhat by other contributions. Somebody always supplied the cigars.

Home of the Academy at New York University, 1850 to 1860

On special occasions, when distinguished visitors from abroad were present, the tradition has it that champagne sparkled and the Astor loving cup was brought from the safe and passed from hand to hand. This glorious example of the goldsmith's art was presented by the first Mrs. John Jacob Astor years ago, through her physician, Dr. Fordyce Barker, who brought so many of the four hundred into this world of joy. Of course, the Loomis collation and all its traditions will be transferred to the new home. With it, too, will go the jolly, fat legged refectory table—on which so many feasts have been spread. From the pantry, connected by dumb waiters with the kitchen below stairs, viands and beverages will be passed to the guests in the collation room, in the large reception room, or to those who may find it convenient to sit or stand in the grand hall.

Home of the Academy from 1875 to 1889, 12 West Thirty-first Street

Many of the choicest treasures of the Academy will be displayed in the cases built into the walls of the exhibition-collation room, or on tables which can be removed quickly when festivities are in order. As a museum in miniature, this apartment with its softened walnut trim, and opening out on the travertine walled hallway, will be a delight to all interested in the arts. Here, indeed, a collector's paradise is in prospect. The medical incunabula are famous. Among the classic works, in perfect preservation, are Albertus Magnus's *De Animalibus* bearing date of 1497; the Expositiones of Ferrarus, 1494; choice volumes of Rhazes, with fifteenth century imprints; and editions of the books of Pliny, the Younger, from the press of the Renaissance. In these cases, too, will be the instruments used by some of the world's greatest surgeons, worth more than their weight in gold by reason of their association with pioneers who devised them to ease human suffering. The collection of Dr. Valentine Mott, distinguished surgeon, and member of the highest social circles of old New York, are in the possession of the Academy. In it is a set of amputating knives which he obtained in England when he was studying with Sir Astley Cooper, the noted court physician. Their handles are made from sturdy oak, taken from old London Bridge.



Present home of the Academy, 17 West Forty-third Street

Still on the first floor, we shall find an informal reception room, coat rooms, retiring rooms and all manner of conveniences.

From the large hall we shall be able to go to the auditorium situated in the two story wing and extending upward into the second story with its balcony. The main room will seat 516 persons, the balconies 171 more, thus making seven hundred persons in all. At the side of the stage of the auditorium will be a small conference room for speakers or for use as a dressing room. Booths of metal for stereopticon and moving pictures, telephone stations and other appliances will be provided.

Of prime importance in the life and work of the Academy is its library of more than 327,000 volumes, exclusive of the periodicals, second in this country only to that of the Surgeon General in Washington. This storehouse of medical lore is not only available for the members of the Academy, but also to physicians from everywhere, and until two o'clock in the afternoon, on week days the rules provide, the general public is admitted. The stacks for the books will begin on the solid rock in the subbasement, and extend up through basement and the three floors.

They will consist of nine tiers each seven feet in height and the total capacity will be enough to take care of the expansion of the library for some years to come. This installation resembles that of the New York Public Library, a startling innovation in its time, which was designed by a physician, the late Dr. John S. Billings, whose deep learning and fine executive ability were of such service to the general public.

The visible part of the library, as far as the non-technical readers are concerned, at least, will be on the third floor in the principal or taller part of the building. From its tall arched windows one may let one's eyes stray

occasionally to the throbbing traffic of Fifth Avenue. The chief reading room will be ninety-five feet by thirty-seven feet and at its six long tables one hundred and sixteen persons can be seated at once. The adjoining journal room will accommodate about sixty more seekers for information. Adjoining the principal reading room will be a members' room. The delivery desk will be on the third floor, just in front of the stack, and on this floor also, over the auditorium, will be the workrooms for the librarians and indexers. The third mezzanine will have the upper parts of the high ceiled and commodious reading and journal rooms, and some small studies. There will be on the open shelves about ten thousand books, works of reference and the more recent bound volumes of medical journals.

Rooms for the meetings of the various sections of the Academy that is, groups of specialists appear on the front part of the second floor and on the fourth and fifth stories. Each of the sections has its large meeting room, attached to which are small apartments, where patients or subjects may be undressed and brought into the meeting room for the examination and observation of those present. Every one of these section quarters will have its screen, its blackboard, and all facilities for showing the x ray plates. There will be also ingenious devices for announcing that some one is "wanted on the telephone."

Several important outside activities will be received into the new fold. As, for example, there will be offices for the New York State and the County Medical Societies on the fourth floor and for the Hospital Information Bureau of the United Hospital Fund on the fifth. The ancient and honorable Society for the Relief of Widows and Orphans and the Physicians' Mutual Aid Association will also be welcomed.

Administration offices will occupy the sixth story. Here will be the office of the newly appointed director, Dr. Linsly R. Williams; the Council Room, and the rooms for clerks and bookkeepers. A special rest room will be arranged for the women workers, with a luncheon kitchen attached. On this floor will be stationed many other agencies through which the Academy extends its mission to all mankind. To this place will be transferred its Committee on Education, which keeps up the standards of the profession. There, too, will be the Clinical Information Bureau, where physicians are informed of operations which they may witness at the various hospitals and thus avail themselves of much valuable material for their own work. It supplements the bulletin boards which will be on the first floor as a guide to the meetings of the Academy and its sections and affiliated societies.

Last, but not by any means least, will be the Public Health Committee of the Academy, which is carrying on the great work of social and preventive medicine; educating the public in hygiene; cooperating with the Board of Health; and doing all in its power to impress upon six millions of New Yorkers the value of radiant, efficient health.

Such will be the new home of the New York Academy of Medicine made possible by philanthropy and dedicated to the highest service of humanity.

220 West Forty-second Street.

An Exhibit at the New York Academy of Medicine of the Works of Sir Thomas Browne

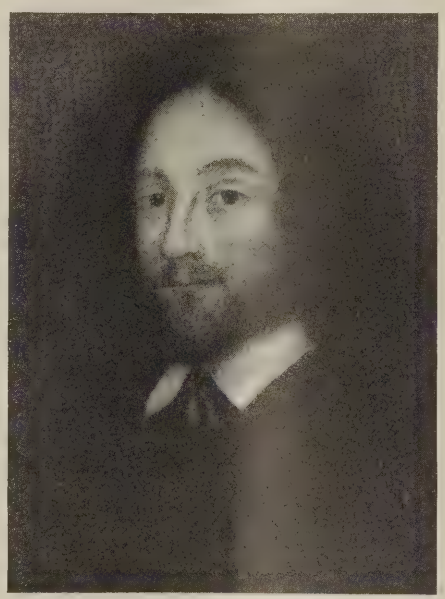
"For the student of medicine, the writings of Sir Thomas Browne have a very positive value," writes Sir William Osler in his biographical sketch of the great English philosopher and physician included in that fascinating volume, *An Alabama Student*. "The charm of high thoughts clad in beautiful language may win some readers to a love of good literature; but beyond this is a still greater advantage. Like the *Thoughts* of Marcus Aurelius and the *Enchiridion* of Epictetus, the *Religio* is full of counsels of perfection which appeal to the mind of youth, still plastic and unhardened by contact with the world. Carefully studied, from such books come subtle influences which give stability to character and help to give a man a sane outlook on the complex problems of life. Sealed early of this tribe of authors, a student takes with him, as *compagnons de voyage,* lifelong friends whose thoughts become his thoughts and whose ways become his ways. Mastery of self, conscientious devotion to duty, deep human interest in human beings—these best of all lessons you must learn now or never; and these are some of the lessons which may be gleaned from the life and from the writings of Sir Thomas Browne."

Sir Thomas Browne was born in London on October 19, 1603, in celebration of which an anniversary exhibit of his works is being shown at the New York Academy of Medicine. He could lift up one hand to Heaven, he says, that he was born of honest parents, that modesty, humility, patience, and veracity lay in the same egg, and came into the world with him. We have very little accurate information about his early years. His father was a London merchant, whose portraits show him to have had a fine presence. His mother was married a second time to Sir Thomas Dutton, a man of wealth and position, who gave his stepson all the advantages of education and travel in his youth. The young Thomas attended school at Winchester and went to Pembroke College, Oxford. It is not known how he happened to take up the study of medicine. He visited Ireland and spent two years traveling and studying on the Continent. Sir William Osler is of the opinion that he must have made good use of his opportunities, since he was able to boast, very modestly, that he was conversant with six languages.

He returned to England in 1634 and settled at Shibden Dale, near Halifax, and it was here that the *Religio Medici* was written. He makes it clear to us that the book was written while he was still very

young. In 1637 he went to Norwich to live, and there spent forty-five years as a student practitioner, with his chief interests centred in his family, his friends, his studies and his patients. In 1641 he married Dorothy Mileham, "a lady of such symmetrical proportions to her worthy husband that they seemed to come together by a kind of natural magnetism." There were ten children. Edward, the oldest of the boys, followed his father's profession and was made president of the Royal College of Physicians. Edward's son, "Tommy," also became a physician and practised with his father.

Sir Thomas was a staunch Royalist. He refers to the execution of Charles I as "a horrid murther" and he considered Cromwell a usurper. In his writings he was discreetly silent on the subject of the Civil War. His rule of life he expressed in a bit of advice to his son: "Times look troublesome, but you have an honest and peaceable profession which may employ you, and discretion to guide your words and actions." He was quite in accord with modern psychological theories in his opinions on education, for he urged his children to form early habits of independence, and sent them abroad young. His son, Thomas, was sent to France alone at the age of fourteen. He tells of his boys to "cast off *pudor rusticus* and to have a handsome garb of his body." The girls also were sent to France.



SIR THOMAS BROWNE

In 1671 he was knighted by Charles II, and in 1664 made honorary fellow of the Royal College of Physicians. His correspondence shows that he numbered among his friends and acquaintances many of the leading men of his day. He was most generous to his family and friends, and contributed largely to educational and other public causes. Sir William Osler says of him: "A life placid, uneventful, and easy, without stress or strain, happy in his friends, his family, and his work, he expressed in it that harmony of the inner and of the outer man which it is the aim of all true philosophy to attain, and which he inculcated so nobly and in such noble words in the *Religio Medici* and in the *Christian Morals.*" His friend, Sir John Whitefoot, wrote of him: "He was never seen to be transported with mirth or dejected with sadness; always cheerful but rarely merry, at any sensible rate; seldom heard to break a jest, and when he did he would be apt to blush at the levity of it. His gravity was natural, without affectation."

He died suddenly on his seventy-seventh birthday from an attack of colic. It had always been one of his pet theories that it was best and most fitting for a man to end his days on the anniversary of the day when his life began, and so it was with him.

In celebration of this, three hundred and twentieth, anniversary of his birth, the New York Academy of Medicine has arranged its interesting exhibit of some of his works and other material of interest concerning the man and his life, which opened on October 19th. A number of the finest of the editions shown are the property of the Academy itself, others were loaned from the medical collection of Dr. Eli Moschcowitz, of New York City, and from other local collections. The material is on exhibition in the reception room of the Academy.

Among copies of the works shown belonging to the Academy of Medicine is a rare Dutch one, *Alle de Werken van Thomas Browne,* printed in Amsterdam in 1688. The volume is characterized by the beautiful and graceful typography, and handsome paper and binding typical of that period of the art of printing. There is a Dutch edition, even earlier—1668—of the *Pseudodoxia Epidemica,* also published in Amsterdam. A German edition of the same work printed in 1680 and very handsomely gotten up is also shown. Among fine modern editions is that of the *Religio Medici* published in New York by the Scott-Thaw Company in 1903. One of the most valuable of the late works relating to Sir Thomas Browne is the beautifully gotten up bibliography of his writings compiled and edited by Dr. Geoffrey Keynes and published by the Cambridge University Press in 1924. The volume is dedicated to Sir William Osler and is unusually artistic in form. Probably no British physician has ever had the following among litterateurs and intelligent laymen that belongs to Browne, as is shown by the large number of popular editions of his works still on the market. Among these are the *Everyman* edition and others almost as well known. He is the only physician included in Edmund Gosse's *English Men of Letters Series.* A number of reprints of his works have been issued as late as 1924.

A large number of the older editions shown in the exhibit are the property of Dr. Moschcowitz. Some of these are very valuable in that they still bear their original bindings; others have been rebound. Among these are some of the earliest editions of the *Religio,* which are supposed to have been published without the author's permission. An interesting feature of Dr. Moschcowitz's collection is a manuscript letter of Sir Thomas Browne's which had never been published until Dr. Moschcowitz's account of it, with facsimile reproductions, appeared in *Annals of Medical History* for September, 1923. The text of the letter was probably written by Browne's secretary or amanuensis, but marginal notes, the signature, and an extra portion of manuscript pasted at the side of the last page are in the great man's own handwriting. The original manuscript of this is shown at the Academy of Medicine.

Among the portraits on exhibition are some from the beautiful collection recently presented to the Academy by Dr. Charles Loomis Dana. Others are

from a collection published in a recent issue of *Biometrika*. These include a family chart and reproductions from photographs of Sir Thomas Browne's skull, which was found by workmen who opened his coffin in the church of St. Peter Mancrott by mistake. The skull was turned over to Dr. Edward Lubbock who presented it to the museum in the Norfolk and Norwich Infirmary, where it is on exhibition bearing a printed slip with the following quotation from the *Hydriotaphia:* "To be knaved out of our graves, to have our skulls made drinking bowls, and our bones turned into pipes, to delight and sport our enemies, are tragical abominations escaped in burning burials."

This makes us think also of Sir Thomas Browne's well known sentence, "Who knows the fate of his bones, or how often he is to be buried?" and of similar sentiments expressed in his beautiful Urn Burial, and Letter to a Friend upon Occasion of the Death of His Intimate Friend, which Walter Pater characterizes as "the best justification of Browne's literary reputation." The Letter to a Friend has recently been reprinted as Number One of the beautiful *Haslewood Reprints*. One of these is shown with the Academy's collection.

Sir Kenelm Digby was Browne's first critic. He not only read the *Religio* through on one night in bed, but on the same night wrote his Observations upon it in the form of a letter to his friend, which extends to three fourths of the side of the *Religio* itself.

These were published in the fifth edition of the *Religio,* dated 1659. Among others of Browne's critics were Samuel Johnson, whose alleged first publication was the *Christian Morals;* Lamb, Coleridge, Pater, and Gosse in his own country; and in America, Ticknor, Fields, Holmes and Lowell. But none has shown keener appreciation than the French critic, Taine, who wrote:

"Let us conceive a kindred spirit to Shakespeare's, a scholar and an observer instead of an actor and a poet, who in place of creating is occupied in comprehending, but who, like Shakespeare, applies himself to living things, penetrates their internal structure, puts himself in communication with their laws, imprints in himself fervently and scrupulously the smallest details of their figure; who at the same time extends his penetrating surmises beyond the region of observation, discerns behind visible phenomena a world obscure yet sublime, and trembles with a kind of veneration before the vast, indistinct, but populous abyss on whose surface our little universe hangs quivering.

"Such a one is Sir Thomas Browne—a naturalist, a philosopher, a scholar, a physician, and a moralist, almost the last of the generation which produced Jeremy Taylor and Shakespeare. No thinker bears stronger witness to the wandering and inventive curiosity of the age. No writer has better displayed the brilliant and sombre imagination of the North. No one has spoken with a more elegant emotion of death, the vast night of forgetfulness, of the all devouring pit of human vanity which tries to create an immortality out of ephemeral glory or sculptured stones. No one has revealed in more glowing and original expressions the poetic sap which flows through all the minds of the age."

News Items.

Staten Island Hospital.—The cornerstone of the new $500,000 addition to the Staten Island Hospital was laid October 17th.

Study of Otosclerosis.—The Carnegie Corporation of New York has granted $90,000 to the American Otological Society for a study of otosclerosis to be conducted during the next five years.

Medical Centre.—It is announced that Sloane Hospital for Women and the Vanderbilt Clinic, New York, will become members of the new medical centre.

Malaria Study.—A study of malaria is to be carried on for several months by the Public Health Service, in Polk, Hillsborough, and Citrus Counties, Florida.

Anniversary Lecture at New York Academy.—The Anniversary Discourse of the New York Academy of Medicine will be delivered November 19th, by Dr. George E. Vincent. His subject will be The Doctor and the Changing Order.

Gift to University of Pennsylvania.—There have recently been placed in Houston Hall the sword of Dr. John Houston, surgeon during the Revolution, and his diploma from Glasgow University. Doctor Houston was a graduate from Pennsylvania in 1769.

New Health Centre.—A gift of $75,000 from Mrs. Leopold Wineman will be used for the Wineman Memorial Health Centre of Detroit, taking the place of the North End Clinic of the Jewish Charities.

Course in Physiotherapy.—A six weeks' clinical course in physiotherapy to be given to graduate students by Columbia, at the Beekman Street Hospital, is planned beginning November 9th. Information may be obtained from the dean of the School of Medicine of Columbia.

Harvey Society Lecture.—Dr. John Northrup, of the Rockefeller Institute for Medical Research, will deliver the second Harvey Society Lecture at the New York Academy of Medicine on Saturday evening, November 14, 1925, at eight-thirty. His subject will be Pepsin and Trypsin.

Graduate Clinics in Chicago.—The Norwegian-American Hospital has arranged a series of graduate clinics for the winter months, covering regional anatomy, physical diagnosis, internal medicine, and urology, and also case presentations and pathologic conferences. Dr. Harry Noskin is in charge of the programs.

Examination for Psychologist.—A position is open in the U. S. Public Health Service, Atlanta, as associate psychologist at Atlanta, Georgia, for the study of the mental status of negro school children. The entrance salary is three thousand dollars; a medical degree is not required. Information may be obtained from the U. S. Civil Service Commission.

Gifts to Jefferson Hospital.—The will of the late Simon Gratz of Philadelphia provides several gifts for Jefferson Hospital, $50,000 for a private room for the care of school teachers, free of charge; $7,000 to be awarded to a graduate doing within five years the most important work in the advance of medical or surgical treatment of disease, or research; $20,000 for the endowment of four beds in memory of members of his family.

Lane Lectures.—The Lane Lectures of the Stanford University Medical School, San Francisco, will be given November 9th to 13th, by Dr. Vittorio Putti, professor of orthopedic surgery of the University of Bologna and director of the Rizzoli Institute. His subjects will be, Congenital Dislocation of the Hip; Arthroplasty, History and General Considerations; Technic of Arthroplasty; Pathogenesis of Sciatic Pain; and The University of Bologna in the History of Medicine.

Child Mortality Rate.—A study has been made by the U. S. Children's Bureau of the effect of a law passed in 1916, in Maryland, prohibiting separation of mother and baby in the first six months of the child's life. Before the law, one of every three babies of unmarried mothers died the first year; one out of four, in the first six months. The death rate now is one of eight babies of unmarried mothers during the first year and one of twelve during the first six months; a reduction of more than fifty per cent. The death rate of legitimate infants was reduced about twenty per cent. during the same period.

National Medical Congress.—The Philadelphia County Medical Society is planning to issue invitations for a national medical congress, to be held next year in connection with the sesquicentennial celebration taking place in the city next year.

Sternberg Medal.—As a memorial to the late George M. Sternberg, a former surgeon general of the United States army, Mrs. Sternberg has donated a medal to be awarded yearly to the student at the University of Michigan Medical School who makes the best record in preventive medicine.

Chicago Surgical Society.—This organization celebrated its twenty-fifth anniversary with a dinner at the Hotel Sherman, October 2d. The speakers were charter members of the society. A testimonial address to the late Dr. Albert J. Ochsner was delivered by Dr. Edward Wyllys Andrews.

Pediatric Societies Meet.—The New England Pediatric Society, the Pediatric Section of the New York Academy of Medicine, and the Philadelphia Pediatric Society held a joint meeting in Philadelphia, October tenth. A symposium was held on Posttonsillectomic Pulmonary Abscess, as part of the meeting .

Smallpox Survey in Kentucky.—A study recently made by the state board of health showed there had been 1,700 cases of smallpox during the fiscal year ending June 30, 1925; 150 of these were severe and eight fatal. About thirty per cent. of the school children of the state had been successfully vacinnated. The board of health declared an emergency to exist and called for an enforcement of the state laws requiring vaccination as a requisite for school attendance.

Cincinnati Hospital Survey.—A study recently completed by the Helen S. Trounstine Foundation of Cincinnati, at request of the community chest, showed eighteen private hospitals with 2,110 beds; three municipal hospitals with 1,140 beds; and twelve proprietary hospitals with 355 beds. Among the recommendations of the survey are better facilities for convalescent care and for treatment of chronic patients; and also the formation of a hospital council representing the hospitals, the academy of medicine, and the public.

Italy Honors American Stomatologists.—At the official reception, given at the Department of Health in Rome to the American Stomatological Committee, a parchment of the Seventeenth Century was presented to the American Stomatological Association, as a token of honor to the American pioneers in recognition of their assistance to the Italians, in their fight for the revocation of the 1923 Dental Law. This parchment and a report of the Committee's activities were presented at the meeting of the American Stomatological Association, on October 15, 1925.

Personal.—Dr. Wilfred M. Post of Williston, Long Island, has been awarded the Near East Relief medal for distinguished service, for his work during the typhus epidemic at Constantinople in 1922 and during the Smyrna disaster.

Dr. Nathan Ratnoff will be guest of honor at a testimonial dinner to be held at the Hotel Roosevelt, November 24th. Tickets may be obtained from Dr. Joseph Bieber.

Dr. Simon Flexner, Dr. George E. Vincent and Dr. H. S. Pritchett, of New York, attended the semi-centennial celebration of Vanderbilt University, Nashville.

Dr. Alton S. Pope has been appointed assistant professor of epidemiology at the Institute of Public Health of Columbia, and Dr. Frank G. Pedley, assistant professor of industrial hygiene.

Dr. Grace S. Weightman, of Chicago, has been appointed chief of the division of child hygiene and public nursing of the Illinois Department of Health.

Mr. John S. Brownne, for forty-four years librarian of the New York Academy of Medicine, has retired, becoming consultant librarian. He was presented with a purse from the members of the academy, and an engrossed resolution.

Dr. John J. Lambert, for thirty years on the faculty of the University of Iowa College of Medicine, has resigned to become associated in practice with his brother, Dr. Charles I. Lambert, of New York.

Dr. Hallowell Davis, of Boston, has been appointed by Harvard to aid and advise premedical students in planning and correlating their work in preparation for medical studies.

Dr. Samuel B. Grubbs, of the U. S. Public Health Service, has been detailed assistant surgeon general in charge of foreign and domestic quarantine and immigration.

Society News and Notes.

The Southern Medical Association meets at Dallas, Texas, from November 9th to 12th.

* * *

England has a Medical Golfing Society which holds annual tournaments and affords other social and recreational opportunities to its members. In the tournament held last summer nearly a hundred members participated.

* * *

The American Association for Medical Progress, in commemoration of the anniversary of the death of Pasteur on September 28th, distributed to principals and heads of biology departments of high schools a leaflet entitled, How Pasteur Convinced the World. With this the Association sent out a memorandum of Pasteur's outstanding achievements, with suggestions about suitable programs celebrating Pasteur's work for pupils to take part in without devoting too much time to preparation. A large number of schools responded and gave special programs to commemorate the anniversary.

* * *

Dr. Pierre Janet of France was guest of honor at an afternoon tea at the New York Academy of Medicine on Friday, October 23rd, given by the Neurological Section of the Academy and the New York Neurological Society. The reception committee consisted of Drs. Charles Loomis Dana, Foster Kennedy, Bernard Sachs, L. Pierce Clark, M. Allen Starr, Frederick Peterson, Frederick Tilney, I. Abrahamson, and Charles A. McKendree.

* * *

The first International Congress on Malaria was held at Rome, October 4th-6th.

* * *

The *Medical Press and Circular* makes the announcement that Lord Dawson of Penn, physician to H. M. the King, has left London for Canada and the United States in order to visit some of the hospitals and medical schools in America. Lord Dawson will be guest of honor of leading American societies and institutions.

* * *

The Report of the New York Association for Improving the Condition of the Poor for the year 1924 deals with 5,693 families composed of more than ten thousand adults and nearly twenty thousand children. The report shows noteworthy gains in clinic care, nutrition instruction, hospital care, and mental examinations, and a decided drop in maternity cases, convalescent care, and physical treatment given by nurses.

* * *

Guests of honor from foreign countries at the recent annual meeting of the Association of Military Surgeons of the United States in New York City were Surgeon Rear Admiral Sutton, C.M.G., of the British Navy; Medical Inspector General J. F. A. Rouget of France, Lieutenant Colonel Dolidan Hulewicz of the Polish General Staff, Dr. Dolybe Coryllos of the Greek Army, now a member of the Polyclinic staff; Colonel Speare, Medical Principal of the French War College; Captain Wao Nagimo and Surgeon Marchimo of Japan; Major Guiseppe Rolando of the Italian Navy; and Drs. José Izquierdo, Surgeon General of Venezuela, Bernardo Schiffrin, L. H. Debayle and Henry Debayle, all from Latin America.

* * *

The National Council of the Young Men's Christian Association held its twenty-first national conference on colored work in Washington, D. C., from October 21st to 23rd. The conference brought together the secretaries and laymen of the colored and white races for discussion and future programs. This was the first conference since that held in Cincinnati four years ago.

* * *

Notable European physicians who recently arrived in this country from abroad are Drs. Martel of France, Eugen Hessler, and Sofie Nordhoff-Jung, all members of prominent Continental medical organizations. Well known medical men who visited New York City recently are Dr. P. Ikeda of the S.S. Havre Maru, Osaka S.S. Company; Sir Donald McGavin, Surgeon, New Zealand Navy; and Dr. W. W. Battey of Augusta, Ga. Dr. Gonzales Pedroso of

Havana, Cuba, a prominent genitourinary surgeon, is to be in New York City during November.

* * *

At the meeting of the New York Academy on October 15th, the Wesley M. Carpenter Lecture was delivered by Dr. Lewellys F. Barker, his subject being The Practical Management of Neurotic Patients. At the meeting of the Section of Genitourinary Surgery of the Academy held on October 21st, Dr. Charles P. Mathe of San Francisco addressed the meeting on The Present Day Status of Urology in Europe. At the meeting of the Section of Obstetrics and Gynecology on October 27th the papers of the evening were read by Drs. Samuel Monash and Ira Wilens; Dr. Joseph W. Draper reported an interesting case of actinomycosis of the tubes and ovaries. At the meeting of the Section of Laryngology and Rhinology on October 28th, cases were presented by Drs. J. D. Whitham, A. Lobell, Frank R. Herriman, Leon T. LeWald, Gouverneur Morris Phelps, and Alfred Schattner.

* * *

A summary of the proceedings of the meeting of the permanent committee of the *Office Internationale d'Hygiène Publique,* held in Paris from April 27th-May 6th, is published in Public Health Reports for September 18th. In attendance were delegates from Australia, Belgium, British India, Czechoslovakia, Denmark, Egypt, France, French West Africa, French Indo China, Great Britain, Italy, Japan, Madagascar, Monaco, Morocco, Holland, Norway, Persia, Peru, Poland, Switzerland and South Africa.

* * *

At the luncheon given last summer by the English-Speaking Union at the Hyde Park Hotel, London, in honor of the American and Canadian physicians touring the British Isles, Sir Arbuthnot Lane made an interesting address in which he emphasized the fact that medical men have much more freedom of expression on medical matters in this country than in England. In almost every American newspaper, he said, one might see medical questions freely and boldly discussed by doctors, but if a doctor were to do that in England he would have the Ethical Medical Committee of the British Medical Association down upon him at once. "It was a perfectly absurd position. The medical profession was at fault in putting up with it. Doctors should stand up against it."

* * *

The fourteenth annual congress of the National Safety Council was held in Cleveland, Ohio, from September 28th until October 2nd. The program consisted largely of a résumé of all the important activities of the Council in the safety field during the year. Special emphasis was laid upon the thorough work done along the line of systematized statistics and coordination of the problems common to organizations working with public safety and industrial hygiene. A joint session was held with the industrial nursing section of the National Organization for Public Health Nursing.

* * *

The Child Study Association of America held a conference at the Waldorf Astoria in New York City, October 26th to 28th, and is holding a ten day institute until November 7th. Among speakers listed are Dr. Bernard Glueck, Dr. Helen T. Woolley, Dean J. E. Russell, Dr. Beatrice Hinkle and other authorities on child problems. Among the subjects discussed are child adjustment, parenthood, child training, mental hygiene, delinquency, etc.

* * *

The Fifth International Congress of the History of Medicine was held at Geneva from July 20th to 24th, Dr. Charles Greene Cumston, lecturer at the University of Geneva, presiding. The attendance included representatives from most of the countries of Europe except Germany, Austria and Russia, and also a number of physicians from the United States. Dr. Cumston's presidential address was on the subject of some of Geneva's most distinguished physicians, particularly Daniel Le Clerc, whom he characterized as the father of the history of medicine. Dr. J. D. Rolleston read a paper on Voltaire and some of the English physicians, Dr. Comrie spoke on Robert Blythe, to whom was attributed the first clear description of tuberculous meningitis, and Dr. Ernest Wickers Linner discussed the subject of syphilis in Geneva during the latter part of the fifteenth century. Dr. R. O. Moon read a paper on Paracelsus, and Mrs. Lilian Lindsay one on the growth of the science of dentistry in Great Britain from its beginning until the nineteenth century. Among the entertainments provided for those attending the congress were a tour of Lake Geneva, including visits to the Castle of Chillon and Evrais, which was followed by a banquet in the evening terminating the congress. The next congress, it was announced, will be held in 1927 at Leyden, the former home of Boerhaäve and at one time the most famous medical teaching center in Europe.

* * *

The program of the meeting of the American Public Health Association, held at St. Louis, October 19th to 22nd, emphasized in its general sessions a survey of the year's activities in public health work, and an appraisal of the progress made. Among problems of this kind brought up were functions of administration, costs, professional relationships, standard practice, etc. Dr. A. W. Freeman discussed the subject of costs, Dr. Henry Field Smyth that of progress in industrial hygiene, Dr. W. F. Walker read a paper on advances made in sanitary practice, and Dr. C. J. Hastings one on the future of humanity from a public health point of view. Perhaps the most interesting feature of this meeting was the opportune arrangement of joint sessions for related groups which could thus discuss their common problems. Among these joint sessions was that of industrial hygiene and public health, including discussion of interstate control of poison hazards other than those of food products; and that of sanitary engineering, including air pollution, lighting, and the dangers of carbon monoxide. Another joint session was that of nursing, public health and administration, and a third on epidemiology, including adminstration, sanitary engineering, and vital statistics, with particular attention to the problems of influenza, respiratory disease control, measles, scarlet fever, diphtheria and other epidemic diseases. The forum session was of special interest, since it gave prominence to the subject of free service and statistical evidence of successful health effort.

* * *

The cornerstone of the new building for the New York Academy of Medicine on the corner of Fifth Avenue and 103rd Street was laid at four thirty o'clock on the afternoon of Friday, October 30th. A large number of members and their guests attended the ceremony.

* * *

The Association of Military Surgeons (international), which met in New York City, October 8th-10th, included representatives from many foreign countries, including Japan, Italy, France, Poland, and Great Britain. On the Sunday following the close of the meeting, the delegates and their friends enjoyed an excursion up the Hudson to West Point, where they were the guests of the Military Academy.

* * *

Well known physicians who will visit this country in the near future are Doctor Putti of Bologna, an associate member of the New York Academy of Medicine, and Sir Arbuthnot Lane, who will address the College of Surgeons of Philadelphia.

* * *

In September of 1924 Dr. E. Sergent, of the Faculty of Medicine of Paris and member of the Academy of Medicine, came to Canada as head of a French delegation, including among other distinguished French physicians, Drs. Ribadeau-Dumas, Desmarest, Jeanneny, Joltrain, Francis Bordet and Lescaret. Dr. Sergent had been invited by the government of the Province of Quebec to give a course on tuberculosis at Laval University in Quebec and to the Faculty of Medicine of Montreal. Dr. Ribadeau-Dumas was invited to give at the same time a course in child training. Their trip coincided happily with the time of meeting of the Eighth Congress of Physicians of the French Language of North America, thus enabling them to bring contributions of interest to the Congress. Their courses have been commented upon as most successful, and the cordial welcome of the French-Canadian doctors was pronounced, both in Quebec and Montreal. Among those attending the Congress were many physicians from MacGill University, and a large number from neighboring cities, including Acadia and New Brunswick. Banquets and receptions both public and private testified to the esteem and sympathy felt toward the French by their French-Canadian cousins. The Congress was a great success, and was attended by nearly five hundred.

Book Reviews

EDEMA

L'Œdème. Etude Expérimentale et Clinique. Par J. Le Calvé. Paris: Masson et Cie, 1925. Pp. 648.

In this voluminous monograph the author attempts to establish the thesis that in the genesis of all edemas and serous effusions a vasomotor reaction is the primary cause, and that without such a reaction edema does not occur. He conceives of edema as a defensive reaction of the organism to an excess of water and soluble substance which the body cannot dispose of. In support of his theory the author cites many experiments on rabbits, as well as blood analyses on patients made before and after aspiration of effusions in the pleura or peritoneum. He attempts to bolster his theory with many clinical observations of equivocal value. The first part of the book consisting of 195 pages is devoted to the presentation of this point of view. A careful study of this section leaves the reader unconvinced of the validity of Dr. Calvé's hypothesis. One gains the impression that the author attempts to force facts to fit theory. Indeed a number of his generalizations are without adequate foundation, for instance, that polyuria lowers hypertension when the blood mass is increased. A number of statements and expressions of opinion, however, should prove stimulating to the thoughtful reader.

In the second part of the volume the author attempts a complete clinical study (pathology, pathogeny, symptomatology and treatment) of every form of edema. Here, too, although the purely descriptive sections are quite adequate, the author attempts to explain every type of edema by his theory. Thus he says that cardiac edema is primarily determined by toxins generated in the tissues as a result of anoxemia, which toxins act on the vasomotor apparatus. For a book that attempts a comprehensive review of the subject of edema, the bibliography is very scanty and onesided. There is little mention of literature that is not French.

ARTERIOSCLEROSIS

Arteriosclerosis. A Summary View. By the Late Rt. Hon. Sir T. Clifford Allbutt, M.D. London: Macmillan, Ltd., 1925. Pp. 108.

Sir Clifford Allbutt died on February 22, 1925, in his eighty-ninth year. This booklet was completed a few weeks before his death and is remarkable chiefly as evidence of his undiminished intellectual powers, and indefatigable labors even at this advanced age. He must have been a constant reader of medical periodicals to the very end, for in this work the literature of the last few years is thoroughly covered; indeed the last paper referred to was published in January, 1925. This small treatise is based on a lecture to a Postgraduate class in Cambridge and although entitled "Arteriosclerosis" concerns itself more particularly with essential hypertension or "hyperpiesia," as Allbutt called it. Allbutt was one of the first and the leading English writer to distinguish the group of patients characterized by hypertension unassociated with kidney disease and to insist on differentiating their disorder from the socalled nephritic hypertension. In this volume he again summarizes the evidence supporting this view, which he developed extensively in his two volume work published in 1915. He emphasizes the lack of relationship between arteriosclerosis of the larger arteries (which he has termed "decrescent arteriosclerosis") and hypertension. As a therapeutic measure he has found diathermy the most valuable immediate aid in hyperpiesia. As a summary of the fundamental clinical facts about arteriosclerosis and hypertension by an old and distinguished clinician, this volume should find a large sphere of usefulness.

STOMATOLOGY

Maladies de la Bouche. Par le Dr. R. Nogue. Traite de Stomatologie. Illustre. Paris: J.-B. Bailliere et Fils, 1924.

This book is the seventh volume of the classical system of stomatology by Gaillard and Nogue. It is a complete and scholarly work of almost five hundred pages, illustrated with sixty-five figures. The volume is divided into five large sections as follows: General considerations, semeiology of the mouth, diseases of the lips, diseases of the buccal cavity, diseases of the tongue. Its greatest lack, particularly to the foreign reader, is the absence of an index. This negative feature the book shares with other French publications. It is hoped that future editions will remedy this defect.

The work should make a strong appeal to both physician and dentist.

SURGICAL DYSPEPSIA

A Textbook of the Surgical Dyspepsias. By A. J. Walton, M.B., B.Sc., F.R.C.S. Illustrated. London: Edward Arnold & Co.; New York: Longmans, Green and Company, 1923. Pp. 728.

The splendidly illustrated volume is a welcome contribution to the subject. The author gives every evidence of deep study, thorough familiarity with his field and careful judgment. The presentation is excellent and easy to follow. The bibliography is unusually complete in references to the medical as well as the purely surgical literature.

The subjects treated include surgical anatomy of the various digestive organs, methods of examination, gastric ulcer, duodenal ulcer, pyloric stenosis, gastric neoplasms, diseases of the liver, gallbladder and pancreas, appendix dyspepsia, and visceroptosis in both its medical and surgical aspects.

The book can be heartily recommended for careful perusal by the medical as well as by the surgical student in this field.

CLINICAL DERMATOLOGY

Cliniques Dermatologiques. P*rofessées Dans Les Hôpitaux de Paris (La Rochefoucauld Broca-Pascal-Saint-Louis) et a la Faculté de Medicine de Strasbourg.* Par Dr. L Brocq. Paris: Masson et Cie, 1924. Pp. 739.

All who are interested in dermatology recognize the high position held by Brocq as a teacher and author. He is perhaps best known to the average physician as the author of rather voluminous didactic works on dermatology. The numerous publications which have appeared for many years in the *Annales de Dermatologie et de Syphilographie* and the *Presse Médicale* are by no means so well known. The present volume is practically a collection of such scattered publications and is in no sense a textbook. It

is essentially a clinical treatise founded on the author's long and varied hospital experience. Some of the chapters are reprints of published articles. Some others appear in print for the first time. At the end of the book is found a classified list of the author's writings which form the basis of this volume.

The various chapters are divided into general considerations, parasitic and microbic diseases, the causes of which are apparently known, and cutaneous reactions, an expression applied to that still numerous class of skin diseases in which the causation has not been definitely established. As a philosophical treatise on the etiology of the more important skin diseases, their diagnosis and treatment, the book will be found of value to the more advanced student of dermatology. It is not a useful book for the casual reader or undergraduate student. The text is illustrated by fifty-four black and white photographs, the majority of which are excellent.

BLOOD CHEMISTRY

The Chemistry of the Blood in Clinical Medicine. By O. L. V. De Wesselow, M.B., F.R.C.P. New York: William Wood & Company, 1925. Pp. 255.

Chemical analysis of the blood as an integral part of the routine clinical examination of patients only became possible with the development of the socalled micromethods. Credit for the development of such methods belongs largely to American workers. One result of this achievement of American medicine has been the uncritical worship of blood chemistry estimations by American practitioners. All too often the physician, lacking knowledge of the significance of the changes in the chemical constituents of the blood, leans on the laboratory with the whole weight of his uncritical optimism and expects it to solve for him all matters of diagnosis, treatment and prognosis. In this excellent volume Dr. De Wesselow reviews clearly and accurately the chemistry of the blood in clinical medicine. One after another all of the important chemical constituents of the blood are discussed. A presentation of the important facts of the normal metabolism is followed by a discussion of the significant changes that occur in disease. Chapters are devoted to acidosis and alkalosis, blood sugar, nephritis, tetany, rickets, gout, fats and anoxemia. In a final chapter the important analytical methods are described. A short, well chosen bibliography appears at the end of every chapter. The book should find a wide field of usefulness.

PRINCIPLES OF OPHTHALMOLOGY

Causeries d'Opthalmologie. Documents pour les Praticiens. Par A. Cantonnet. Paris: A. Màloine, 1925. Pp. 325.

A sort of a popular exposition of elementary principles of ophthalmology made up of the author's lectures before his students, and of various medical articles, systematized and collated so as to make interesting reading for the general practitioner. Considerable ground is covered, and the matter is brought up to date, so that even the specialist may profit by going over certain chapters, such as red free illumination, examination of the eyes of aviators, etc. The whole is written in the clear, precise and easily readable French style, that recommends itself even to such English readers who do not have a perfect control over their French.

NUTRITION

The Newer Knowledge of Nutrition. The Use of Foods for the Preservation of Vitality and Health. By E. V. McCollum, Ph.D., Sc.D., and Nina Simmons, Sc.D. Illustrated. Third Edition. Entirely Rewritten. New York: The MacMillan Company, 1925. Pp. 675.

The present is the third edition since this important work first made its appearance in 1918. An entirely new principle—that of the biological, as contrasted with the old chemical, method of food analysis, makes this treatise one of vital interest to the clinician. From such a foundation alone can grow a really adequate concept of "what to eat and why." A refreshing common sense and broadness of vision characterize the entire presentation, as can be seen from such a passage as the following:

"The tendency of those who have investigated the relation of the diet to disease has been to assume that a diet which does not lead to clinically recognizable symptoms of malnutrition is an adequate one. Now that we understand so much about the nutritive needs of the body and about the properties of food-stuffs we appreciate the existence of many grades of malnutrition. It is becoming constantly more evident that even a slight departure from the optimal in the composition of the food may lead to states of nutritional instability which become contributing factors to physical breakdown when hygienic factors are unfavorable, or when infectious processes are operating. Even under the most favorable living conditions, however, there can be little doubt that under such circumstances the body tissues lose their vitality and the span of life tends to shorten."

The present edition contains new matter on rickets, on the effect of diet on resistance to disease, on iodine deficiency and goitre, and on the dietary habits of man in different parts of the world.

The book is strongly recommended to all in any way interested in nutrition, whether in its theoretical or its practical aspects.

IMMUNITY

The Chemical Aspects of Immunity. By H. Gideon Wells, Ph.D., M.D. American Chemical Society Monograph Series. New York: The Chemical Catalog Company, Inc., 1925. Pp. 254.

This is one of a series of monographs published by the American Chemical Society for two purposes. The first purpose, of interest to chemists, is to present the knowledge available upon a chosen topic in a readable form, intelligible to those whose activities extend along a wholly different line, thereby promoting a closer relationship between subjects apparently not closely related. The second purpose is to promote research in the branch of science covered by the monograph, by furnishing a well digested survey of the progress already made in that field, and by pointing out directions in which investigation needs to be extended. Such endeavors constitute a serious attempt to found an American chemical literature without primary regard to commercial considerations.

Originally the reactions of immunity were studied with the purpose of solving urgent problems concerning the cure, diagnosis and prevention of disease. Then came the growing recognition of their importance as general biological phenomena not exclusively concerned with disease. The chemical significance of immunity was not appreciated because of the unknown constitution of bacteria, blood serum, and cells. The nomenclature proposed by Ehrlich was simply a hypothesis. The early recognition by Bordet of the similarity of the reactions of immunity to the reactions of colloid chemistry probably failed

to impress the rank and file of investigators in immunology, because at that time they could not appreciate the significance of the colloidal chemical viewpoint, for lack of knowledge of this new field of chemistry. With the progress of colloidal chemistry and studies on the behavior of protein solutions more light will be thrown on the problems of immunity resulting in increased knowledge of the subject.

The author presents a digest of the entire subject of immunity from the chemical aspect, so arranged as to constitute not only a summary of the situation, but also to serve as an illustrated guide to the literature dealing therewith. The bibliography is adequate and covers practically all contributions of importance.

The introductory chapter deals with immunological reactions as chemical reactions and the definitions of terms used in immunology. The subjects discussed include antigens, immunological specificity, the nature of antibodies, neutralization of toxin by antitoxin, agglutination and precipitation reactions, the lytic reactions (bacteriolysis, cytolysis, amboceptor complement reactions), the Wassermann reaction and related reactions with syphilitic blood, hypersensitiveness, anaphylaxis and allergy, phagocytic immunity, and resistance to nonantigenic poisons.

The author's style is simple and explicit, rendering the discussions intelligible even to the tyro. Each chapter is ended with a recapitulation which also helps to a better understanding of the subject matter. This monograph may well be used as a textbook on the subject of immunity.

MEDICAL STATISTICS

Statistical Methods for Research Workers. Biological Monographs and Manuals, III. By R. A. Fisher, M.A. London and Edinburgh: Oliver and Boyd, 1925. Pp. 239.

Biology used to be purely a matter of observing and describing the characteristics of living organisms. Francis Galton began the quantitative study of biological phenomena by applying to them the methods of mathematical analysis. At the present time a biologist without some knowledge of the fundamental principles of probability distributions and correlation coefficients is very much at sea when he comes to evaluate the reliability of experimental work for the conditions of variation within a group. Unfortunately, the mathematics of the subject is repellent; unfortunately also the physician has in general no mathematical equipment to start with.

However, a beginning has surely been made, for a surgeon has been heard to say in open meeting that he omitted the second and third decimals from his percentages, because Raymond Pearl said that they were not significant. The surgeon of course was not aware that Raymond Pearl was not the first to say this, nor was he aware that even the figures to the left of the decimal point were not significant, owing to the small number of cases which he had studied, but at least some light has penetrated the medical profession, and after the practitioner has learned to abandon decimals in his percentages, he may ultimately come to test the whole numbers. Almost all medical statistics are vitiated by the lack of knowledge of the simple relations of probabilities, and it is a pity that the contents of a book like Fisher's will never in this generation be made a part of the equipment of the average medical investigator.

HANDBOOK FOR NURSES

Eye, Ear, Nose and Throat Manual for Nurses. By Roy H. Parkinson, M.D. Illustrated. St. Louis: The C. V. Mosby Company, 1925. Pp. 207.

A useful little book written for the benefit of nurses connected with special work on eye, ear, nose and throat. The author's aim to give just enough instruction to the nurse to enable her to understand and follow the directions given by the physician, has been fully achieved. The book is divided in two principal parts, the first of which deals with the essentials of the anatomy and physiology of the parts, in short, concise paragraphs, while the rest is devoted to the description of the diseases and their treatment, as far as the nurse may be concerned therein. The concluding chapter on public health in its relation to the work of the school and district nurses, gives in a condensed and easily readable form a great deal of valuable information concerning the handling of eye, ear, nose and throat problems in school children.

LABORATORY MANUAL

Laboratory Diagnostic Methods. Pathological, Bacteriological, Serological and Chemical. By John A. Kolmer and Fred Boerner. New York and London: D. Appleton and Company, 1925. Pp. 338.

This is an extremely well prepared, concise and useful manual for the laboratory worker. Almost every type of laboratory examination required is described, including some which are not frequently found in such volumes, such as tests for liver function by the methods of Piersol and Bockus, and of Rosenthal, and Widal and Abrami's hemoclastic crises tests. The new Kolmer qualitative and quantitative tests for syphilis are very clearly explained. The book is an admirable guide to diagnostic procedures, and will be found helpful in this field. It is conveniently interleaved, well indexed, and altogether fulfills its purpose excellently.

Medicoliterary Notes.

A union list of foreign serials cited in the Psychological Index for 1922, currently received in 114 libraries, has been issued in mimeographed form to subscribing libraries by the Research Information Bureau of the National Research Council, Washington, D. C.

* * *

The Board of Health of North Carolina is publishing a new four page bulletin entitled *Constructive Medicine* for the physicians in the State. The whole field of health promotion is covered, with emphasis on the relating of the special problems of public health workers to those which are at the same time the problems of the doctors.

* * *

In a recent report of the New York Association for Improving the Condition of the Poor, it is stated that approximately seven tons were added to the weight of three thousand children from the slums and tenements, who went to the association's summer camps during the past season. Each child gained an average of four pounds and eleven ounces. The report tells us that 5,200 mothers and children spend 75,430 days in the country and at the sea shore as the association's guests. The outings cost $81,490, which was contributed by 4,828 persons.

* * *

That emotion felt by an audience causes a rise in room temperature has long been believed, but actual records are difficult to find. However, during the memorial exercises for the late President Wilson records were kept and a report made by S. Homer Woodbridge in the *Heating and*

Ventilation Magazine. In the House of Representatives, where the services were held, there is an air supply of 64,000 cubic feet a minute, each six minutes' supply equalling the cubic contents of the hall. The thermometer used was graduated to tenths of degrees, and the temperature was recorded at five minute and finally at two and a half minute intervals. The temperature of the air as it entered the hall averaged 70.5 degrees, the temperature of the escaping air being 72.25 degrees. By the time the assembly of 1500 had settled, the temperature was 72.16. degrees. There was slight variation in the temperature according to the interest and nervous tension of the audience; as the address neared its climax and the tension became greater, the temperature rose suddenly. In five minutes it changed from 72.51 degrees to 75.3 degrees, an increase of 2.79 degrees. The applause, the rising of the audience, and the arrangement of clothing released still more warmth. Immediately following the close of the address and during the music which followed, there was a sharp drop in temperature.—*Nation's Health.*

* * *

A new campaign to eliminate diphtheria in the Bellevue-Yorkville district of New York City is being conducted by the Milbank Memorial Fund in cooperation with the New York City Department of Health. The Metropolitan Life Insurance Company is assisting by the distribution of fifty thousand leaflets on the subject of diphtheria, and all the private physicians in the district have been furnished with antitoxin free of charge. The campaign is in charge of Dr. L. D. Bristol and Bailey B. Burritt, representing the Foundation, and Dr. William H. Park and Dr. John Oberwager of the Department of Health.

* * *

The U. S. Department of the Interior has announced that three new hospitals and an addition to a fourth will be constructed for the American Indians. These will be located at the Klamath reservation in Oregon, at Fort Peck, Montana, at Pyramid Lake, Nevada, and the hospital at Fort Lapwai, Idaho, will be enlarged with a building of fifty beds.

* * *

A late issue of the *Manchester Guardian Weekly* comments humorously and rather gloatingly on the results of the tests recently made in this country anent the affects of cigarette smoking, and mentioned in a late number of the *British Medical Journal.* The conclusion drawn by the experimenter was that cigarettes acted both as a stimulant and as a sedative to the sensory mechanism. When that mechanism was below par, the smoking toned it up; when it was overstrung, it calmed down. "The comment of the *British Medical Journal* is that 'it would appear that tobacco smoking favours the maintenance of, or return to, a normal frame of mind.' This, roughly, is what most smokers hope when they light a cigarette or fill a pipe. But it is nice for them to have their primitive and unguided aspiration confirmed by means of electrical stimuli and sensory thresholds. When the grandmother has been tought to suck eggs, it is at least gratifying to have the success of the old lady's performance adequately established by a well equipped and impartial investigator."

* * *

Boston is to have a *Year Book,* a volume of about five hundred pages, which will present historical data in regard to the development of the city's activities, as well as give descriptions in detail of the work of the various city departments, bureaus and commissions, a review of general social and industrial development, and tables of municipal and community statistics. This will be the first of a series of Boston Year Books.

* * *

The Public Health Laboratory of the University of Amsterdam is to make an exhaustive investigation as to the causes, prevention and cure of one of humanity's worst scourges, the socalled common cold. The work will probably continue until next summer, and will be carried out throughout the whole of Holland by means of the cooperation of eight thousand collaborators.

* * *

The poisonous toadstool has been put in the category of a criminal by the Paris police, according to the New York *World.* A squad of experts has been organized to aid in keeping the deadly fungus, often eaten for the mushroom, out of the kitchen. One group of bluecoats has been stationed in the city markets to pass on all mushrooms sold there, while another group maintains an inspection service station to which the amateur woodsman can take his basket of fungi to get an official O. K. if they are edible.

* * *

Another innovation in France along the lines of public health is the establishment in Paris of a national bureau of public hygiene. Its purposes will be to collect information on the present state of sanitation, hygiene and infectious diseases in the country, so that this information may be made available to students and to the public; to organize in France and in the colonies, educational work for the purpose of teaching measures for the preservation of health; and to coordinate public and private efforts for health protection. The new bureau will be attached to the Ministry of Labor, Hygiene, Charity and Welfare.

* * *

The October issue of *Scribner's Magazine* contains an interesting article on Quackery and Psychology, by Edgar James Swift, whose book entitled *Business Power Through Psychology* has recently been published by Scribner.

* * *

The New York State Board of Regents has granted a charter to the Training School for Jewish Social and Welfare Workers, a national institution which aims to serve the needs of trained social workers throughout the country. The school will be located at 210 West Ninety-first Street, New York City.

According to a recent report of the Health Section of the League of Nations, syphilis has been reduced in Copenhagen, Denmark, from 8.8 per 10,000 in 1910 to 4.6 in 1922. The rate of infection with gonorrhea also shows a considerable decline.

* * *

The Philadelphia Health Council and Tuberculosis Committee has formulated a program of organized health service with the twofold purpose of giving the workers medical attention, and of demonstrating to employers the need of constant medical supervision in their plants. This service includes free examinations at plants during working hours, and free advice and follow up work in the homes.

* * *

One of England's most valued public health officials, Dr. James Niven, was recently found drowned on a beach on the Isle of Man. Dr. Niven was at the time of his death Medical Health Officer of Manchester. The *Manchester Guardian Weekly* for October 2nd publishes not only an obituary notice but also an editorial commenting upon his work and its value to the whole of England, and closing with the statement that, although "very little was publicly known about him, except by a few colleagues, he was one of the men who keep English municipal work an honorable service, and maintain the dignified tradition that a man should give to the world more than he takes from it."

* * *

Recent publications of interest to the medical profession are: *Mental Disorder and the Criminal Law,* a Study in medicosociological jurisprudence, by Sheldon Glueck (Little, Brown); *The Child, the Clinic and the Court,* a group of papers by Julia Lathrop, William Healy, Miriam Van Waters, Franz Boas, Joel D. Hunter, Ben B. Lindsay, Grace Abbott, Herman M. Adler, Julian Mack, F. P. Cabot, and others (New Republic); *One Little Boy,* by Hugh de Sélincourt (Boni): *Vocational Aspects of Psychiatric Social Work,* prepared by the Section of Psychiatric Social Work of the American Association of Psychiatric Social Workers; *Our Enemy the Child,* by Agnes de Lina (New Republic); *The Conquest of Disease,* by David Masters (Dodd, Mead); *How to Feed the Baby,* by Dr. Lena K. Sadler (McClurg); *The Ministry of Health,* by Sir Arthur Newsholme, principal medical officer of the Health Department of England and Wales (Putnam); *The Preschool Age,* by Minnie Watson Kamm (Little, Brown); *Genius and Disaster,* by Jeannette Marks, the main theme of which is the part played by drugs and alcohol in the lives and work of certain famous writers, particularly Coleridge, Rossetti, Poe, Swinburne, James Thomson, Francis Thompson, Elizabeth Barrett Browning and De Quincy, (Adelphi); *The Mind and Its Place in Nature,* by C. D. Broad (Harcourt); *Prometheus or Biology and the Advance of Man,* by H. S. Jennings (Dutton).

Abstracts from Current Literature

BLOOD AND LYMPH GLANDS

Effect of Ultraviolet Irradiation on the State of Serum Calcium.—Alan R. Moritz (*Journal of Biological Chemistry,* May, 1925) describes a method for the separation of the diffusible calcium of the blood serum, consisting of applying a negative pressure of 150 mm. of Hg. on the outside of a collodion sac containing serum and immersed in water. Two c.c. of serum are required, and all of the diffusible calcium is obtained in the filtrate within five hours. Filtration for twenty hours failed to show any further liberation of the colloidbound calcium. Results by this method show a variability of about four per cent., and the method is sensitive to artificially induced changes in the percentage of the diffusible calcium of serum. No changes in the diffusible calcium were found after ultraviolet irradiation of serum *in vitro* and *in vivo*.

Observations on Blood Phosphates as Related to Carbohydrate Metabolism.—A. Bolliger and F. W. Hartman (*Journal of Biological Chemistry,* May, 1925) bring out the following points from the observations recorded: The diabetic state is demonstrated early in the curve of blood phosphates; blood phosphates are depressed during carbohydrate metabolism only when insulin is available; the complete absence of pancreatic hormone is shown by the blood phosphate level which remains unaffected as a straight line during carbohydrate metabolism; as concerns phosphate metabolism, pituitrin is a direct antagonist of insulin; carbohydrates and phosphates are best utilized when there is an excess of each in the circulation.

Combination of Phenol Red and Proteins.—Arthur Grollman (*Journal of Biological Chemistry,* May, 1925) says that the use of phenolsulphonephthalein as a clinical reagent in renal function tests has been criticized for its unreliability due to extrarenal influences. As a result of this investigation, two factors may be clearly defined which will have an extraordinary effect on the rate of the elimination of the dye quite independent of any renal influences. Since the amount of dye held by the serum proteins, and therefore unfilterable, is determined by the albumin percentage composition of the blood and the pH of the latter, these two variables must be considered in addition to the excretion rate. Thus in those pathological conditions in which there is a low albumin content of the blood with a correspondingly low albumin globulin ratio, the amount of dye held in combination with the blood protein is low, and this factor will greatly influence the excretion rate. Grollman has studied the adsorption of phenol red on charcoal and a number of proteins quantitatively, and gives the adsorption curves for blood serum and hydrophilic systems, together with the effect of pH on adsorption by proteins, and these results are compared with those obtained on charcoal.

Determination of Blood Sugar.—Stanley R. Benedict (*Journal of Biological Chemistry,* May, 1925) describes a new method for the determination of blood sugar in which the reagents used are an alkaline copper solution and a complex tungstic acid color reagent, the preparation of which and the technic of the test are given. The new method gives figures averaging some twenty per cent. lower than those obtained by the Folin-Wu method. Glucose added to blood filtrates is recovered satisfactorily by this proposed procedure, and figures by it indicate that the normal blood sugar content averages about 75 mg. in 100 c.c., though Benedict is still of the opinion that the actual glucose content of normal human blood does not usually exceed 60 mg. in 100 c.c., except after a period of food ingestion.

Intraperitoneal Transfusion with Citrated Blood.—David M. Siperstein (*American Journal of Diseases of Children,* April, 1925) emphasizes the fact that the introduction of citrated blood into the abdominal cavity must be regarded as a true transfusion. The good effects of intraperitoneal transfusion cannot be attributed to stimulation of the bone marrow as evidence of such a stimulation cannot be found. Clinical improvement obviously depends on the rate of absorption, which is variable. The basic factors involved are unknown. Physiological processes of obscure origin may be the cause. With the proper preliminary technic, the presence of free citrated blood in the peritoneum is entirely without danger. However, reports of peritonitis and injured viscera following abdominal puncture occasionally appear in the literature, but these are due, for the most part, to faulty technic.

The intraperitoneal transfusion of citrated blood should be regarded only as a substitute for a direct intravenous transfusion. The latter is always the method of choice. The attendant circumstances and the skill of the physician are the deciding factors. If transfusion is indicated and the other routes are unavailable or impractical, the intraperitoneal method may be employed. The harmlessness and the simplicity of technic make this procedure advisable. The clinical results obtained make it practicable.

Etiology of Hemophilia.—J. W. Pickering and R. J. Gladstone (*Lancet,* March 21, 1925) report that the hemophilic bloods examined by themselves coagulated in six to eight minutes at 40° C. This property may possibly be utilized in controlling oozing from wounds and epistaxis. Hemophilic plasma exhibits most of the characteristics of early embryonic plasma. The protective power against clotting of both hemophilic and embryonic blood is not due to the presence of an antithrombin. It appears probable that the delay in the clotting of the hemophilic bloods examined is due to the persistence or reappearance in adult life of an embryonic condition of the plasma, and that in both hemophilic and embryonic blood there is present a relative excess of a stable protective colloid. This conclusion is concordant with the theory of the fluidity and clotting of blood.

Blood Sugar Studies in Fatal Bacterial Anaphylaxis in the Rabbit.—Isolde T. Zeckwer and Helen Goodell (*Journal of Experimental Medicine,* July, 1925) with a view of determining any changes in the blood sugar level in rabbits, produced bacterial anaphylaxis by giving several sensitizing injections of killed organisms and then allowing a period of six to eight weeks to pass, when the injection was given which induced anaphylaxis. It was found that during bacterial anaphylaxis there is a gradual rise in the blood sugar level, which attains an extremely high value at the time of death. The curve of blood sugar is quite similar whether anaphylaxis is induced by organisms which affect the blood sugar in the unsensitized animal or by organisms which have no such effect. No instances occurred in which there was not a marked hyperglycemia in anaphylaxis.

Effect of Deep Therapy on the Blood in Leucemia.—W. L. Watt and J. Carter Braine (*Lancet,* January 3, 1925) draw the following conclusions from a study of eight cases of leucemia subjected to röntgen ray treatment:

1. From the commencement of the exposure to deep therapy radiations the leucocytes begin to fall, and the destruction is most marked during the last half of the radiation.
2. The subsequent fall may be interrupted by a fleeting primary reaction coming on two to five hours afterward, and by a secondary reaction which comes two to five days afterward and usually lasts twenty-four hours.
3. The susceptibility of the individual leucocytes varies with the type of leucemia, in the myelogenous type the myelocyte, and in the polynuclear type the polynuclear cell. However, no matter which type it is, the polynuclear, the lymphocyte, and the myelocyte, if present, all share in the fall, and also in the primary and secondary reactions.
4. With the fall of the leucocytes there is a rise of the red blood corpuscles and the hemoglobin. Conversely, when the red blood corpuscle and hemoglobin fall, the leucocytes rise.
5. The spleen steadily diminishes in size without undue rapidity and without any apparent deleterious effect. Likewise, the liver, when enlarged, and also the lymph glands, similarly diminish in size.
6. The health of the patient steadily improves and in uncomplicated cases, without any serious disturbance of compensation, they are soon back to full time work.
7. Splenectomy is not a contraindication, as the effect is almost as striking as if this organ were present.
8. Patients already subjected to a long course of ordinary x rays, with final failure to respond, are still susceptible to deep therapy with considerable hope of improvement.

The indications for further treatment are the following: 1, any marked increase in the pathological leucocytes, especially when accompanied by a drop in the hemoglobin and the red blood corpuscles; 2, the presence of enlarged glands in other parts of the body which show no signs of diminishing; these should be radiated separately; 3, failure of the spleen to diminish considerably in size, or its subsequent enlargement after having diminished; 4, the general health of the patient deteriorating.

The contraindications for further therapy are: 1, leucopenia; 2, persistent diarrhea, due to an excessive dose; 3, an actual increase of the pathological types of leucocytes after the radiation, unless only a small trial exposure had been given, in which case it would still be safe to give a full sixty per cent. skin dose; 4. deterioration in the patient's general health with failure of the hemoglobin and red blood corpuscles to rise. The liver should, generally speaking, not be exposed to the rays as there is much more liability to röntgen toxemia, a systemic condition with headache, fever, nausea, vomiting, diarrhea, etc. If, however, it is excessive in size and does not reduce with the spleen, small doses (thirty per cent.) to limited areas may be tried. The rays, especially the central rays, should not be directed toward the suprarenals, as they, like the testes and ovaries, are extremely susceptible to the rays.

Attempt to Find an Antipeptic Enzyme in the Blood.—Venice D. Keiser (*Journal of Laboratory and Clinical Medicine,* July, 1925) undertook an investigation of the protective antienzyme theory of gastric protection in view of the fact that peptic ulcer is considered a local autodigestion of the stomach. This theory, if it explains lack of autodigestion, should likewise be applicable to the etiology of peptic ulcer. The methods for demonstrating antipepsin, such as the liberation of dye and protein of Oguro and Hamburger, the gelatin liquefaction method of Sachs, the Matt tube principle, and polariscopic and refractometric methods were tested, and neither proved nor disproved the presence or absence of such a substance. More accurate methods must be devised before the question of the relationship between antipepsin and peptic ulcer can be answered.

Normal Rhythm of the White Blood Cells.—F. R. Sabin, R. S. Cunningham, C. A. Doan and J. A. Kindwall (*Bulletin of the Johns Hopkins Hospital,* July, 1925) found through the use of the socalled supravital technic that the number of the blood cells varies in a definite rhythm. There is an approximately hourly rhythm in the number of the white blood cells, which holds true also for the erythrocytes, platelets, and the reticulated red cells. During the afternoon, regardless of whether lunch has been eaten or not, there is an increase in the neutrophilic leucocytes. The rhythm of the lymphocytes is shorter than that of the leucocytes. A small proportion of the monocytes are normally undergoing division in the circulating blood. In five out of six apparently normal individuals, small percentages of myelocytes were found in the circulating blood.

Hemophilia.—Study of Blood, Clinical Course and Heredity in Three Cases.—Edward C. Davidson and Irvine McQuarrie (*Bulletin of the Johns Hopkins Hospital,* May, 1925) describe a typical, hemophilic family in which fourteen proved cases of hemophilia occurred in eight generations, and give detailed reports of two cases representing the sixth and seventh generations. Two normal female members of the same family presented no evidence of the disease, either clinically or from blood examination. The hereditary transmission occurred in this family according to the law of Nasse. Of the females capable of transmitting the disease 83.3 per cent. are known to have done so. Among the potential hemophiliacs 51.8 per cent. have proved to be bleeders. One typical case of sporadic hemophilia is described, in which the clinical picture and blood abnormalities are identical with those of the hereditary type of the disease. The blood coagulation time and the prothrombin time in the cases of hemophilia were from two to twenty-five times the normal. The finding of Minot and Lee of a qualitative platelet deficiency without a diminution in the number of platelets has been confirmed. The bleeding time, the capillary resistance, the nature of the blood clot when finally formed, the amount of blood calcium and the number of blood platelets were at all times found to be normal. Blood transfusion is the most effective treatment for the hemorrhage in hemophilia, and should be employed as a prophylactic measure preceding surgical operations.

Blood Platelets in the Leucemias.—George R. Minot and Thomas E. Buckman (*American Journal of the Medical Sciences,* April, 1925) maintain that a study of the blood platelets yields useful knowledge for guiding treatment and appraising the state of health of a patient with leucemia. In chronic myelogenous leucemia the numbers of these elements may be normal, enormously increased, or greatly diminished, and in chronic lymphatic and acute leucemia it is the rule to find them below normal. The fluctuations that occur in the numbers of blood platelets are discussed. Petechiæ and other hemorrhages associated with decrease of blood platelets are common, and hemorrhages, but not petechiæ, may occur in chronic myelogenous leucemia when the platelets are much increased.

Localization of a Lesion in the Brain by Differential Staining of Blood Smears.—Akira Sato (*American Journal of Diseases of Children,* March, 1925) asserts that acute lethargic encephalitis is the only disease in which the myeloid leucocytes in a fresh blood smear show a negative peroxidase reaction (copper method) while remaining positive under the oxidase stain of Winkler and Schultze. A bilateral puncture of the corpora striata is described which leads to a similar blood picture. This puncture has been named "peroxidase puncture." These facts have a reverse application, namely, a patient whose blood shows this characteristic staining reaction must suffer from a bilateral lesion of the corpora striata.

Influence of Sodium Chloride upon the Level of Blood Uric Acid.—Victor John Harding, Kathleen Drew Allin, and H. B. Van Wyck (*Journal of Biological Chemistry,* November, 1924) report that fifteen grams of sodium chloride added to a protein or carbohydrate diet lower the level of blood uric acid, and cause an increase in the sodium chloride in the blood, a decrease in serum proteins, and a total retention of water and sodium chloride. The decreased concentration of uric acid in the blood is believed to be due to an increased hydration of the blood, resulting in increased elimination of uric acid. On a constant sodium chloride intake little difference is found in the level of the blood uric acid when on protein or carbohydrate diet.

Nature and Significance of Reversible Hemolysis.—Wilhelm Starlinger (*Wiener klinische Wochenschrift,* November 20, 1924) states that inasmuch as the stroma of the red blood cells bears a negative electrical charge, additional cations must be adsorbed from it, as the absence of precipitation of concentrated heavy metals in the presence of the stroma can be explained in no other way. As a result of the adsorption of the cations, the stroma undergoes a change to a positive electrical charge, and the hemoglobin present in the solution, which receives a negative charge through the anion, is partially resorbed. This explans the immediate rapidity of the course of the reaction (ionic reaction!) and also the exclusive influence of the ionic values. In the same way it explains the slighter power of reaction of the defibrinated unwashed blood, in view of the electropositively charged fibrinogen (or fibrin), which is most probably precipitated partially during the course of the coagulation upon the surfaces of the red blood cells, and which may reduce extensively the primary negative charge of the same.

Noninfectious Leucocytosis.—O. H. Perry Pepper (*Medical Clinics of North America,* November, 1924) states that the three main groups of leucocytes have distinct characteristics and apparently distinct functions. These are: 1, the granular leucocytes—neutrophilic, eosinophilic, and basophilic; 2, the monocytes, and 3, the lymphocytes. The group characteristics of the granular leucocytes include rapid ameboid movements, phagocytic power, a proteolytic ferment, and a responsiveness to specific chemical stimuli. The neutrophil acts as a defense against most types of bacterial invasion; the eosinophil is in some manner related to the disposal of foreign protein in the body, and the function of the basophil is unknown.

The monocytes (large mononuclear leucocytes, transitional leucocytes, endothelial leucocytes) are as a group characterized by marked activity in the phagocytosis of particulate matter; they are capable of slow movement and they possess oxidase granules perhaps indicative of the presence of proteolytic ferment. They form an important part of the socalled reticuloendothelial system and have much to do with the destruction of wornout erythrocytes and with the

breakdown of hemoglobin. The lymphocytes enter the lumen of the intestine, there to be destroyed and to perform some still unknown function. Apparently they are in some way related to certain forms of immunity and bodily resistance, including that to tuberculosis and possibly to cancer. As a group they are peculiarly sensitive to röntgen rays and to radium emanations.

From these brief remarks it must be clear that to think of leucocytosis as always of the same type and always caused by infection is a very inadequate appreciation of the facts. Leucocytosis may result from a wide variety of causes besides infection; it may occur to a slight degree without any change in differential count and without the appearance of any immature or any marked increase in young forms. For the proper analysis of a leucocytosis these various considerations must be kept in mind. In practical everyday medicine the leucocyte count plays an important part, and we must constantly be on our guard not to be misled by it. In the great majority of cases there is little danger of error, but occasionally, as in cerebral hemorrhage, ruptured ectopic gestation and in paroxysmal tachycardia, all showing leucocytosis, the danger of serious diagnostic error is very real.

PEDIATRICS

Bacteriology and Specific Treatment of Infantile Bronchopneumonia.—A. Dufourt (*Presse Médicale,* June 20, 1925) reports bacteriological studies in over one hundred cases of bronchopneumonia in nurslings. The cultures were made from material obtained by direct puncture of the lung with a fine needle during life or from urine obtained by catheterization. The pneumococcus and enterococcos proved to be by far the commonest pathogenic agents. The writer agrees with Thiercelin and Rosenthal that the enterococcus is a very frequent factor in bronchopneumonia. Cultural features and agglutination studies are the only reliable means of differentiation, the morphology being often ambiguous. The enterococcus forms far more resistant cultures than the pneumococcus or streptococcus, readily living three or even six months without subculturing. It grows well in bile media, is not hemolytic, turns esculin agar black in one or two days, and is not agglutinated by antipneumococcic serums. Streptococci are not responsible for more than ten to twenty per cent. of bronchopneumonias, and these cases are nearly always secondary. The Pfeiffer bacillus and the catarrhalis and tetragenus organisms seemed to have little or no etiological rôle, and were always combined with the enterococcus or pneumococcus. Bronchopneumonias with small, scattered, stable foci are usually due to the enterococcus. The massive, pseudolobar forms are due either to the pneumococcus or the streptococcus, the former, however, generally leading to stable foci, while in the latter the involvement is apt to be serpiginous, with progressive displacement of the main seat of disease. The temperature curve in streptococcus bronchopneumonias simulates that of puerperal infection, with successive rises of a few days separated by descents nearly to normal, whereas the pneumococcus leads to a more even curve or plateau condition, and the enterococcus leads to rather irregular and sometimes extensive oscillations, but without the definite remissions or the sudden sharp ascents of the streptococcic cases. The latter cases run a more protracted and tedious course, are prognostically less favorable, and leave the children who recover profoundly anemic. Good therapeutic results were obtained in the author's cases of bronchopneumonia with vaccines, serums or both. The vaccine finally found best consists one third of pneumococci of Types I, II and III; one third or more, of various strains of enterococcus, and the remainder, of staphylococci and tetrangenus germs. The vaccine is sterilized by heat and contains about one billion germs to the mil. Of thirty-six cases of bronchopneumonia, including twenty-eight below two years of age, treated with this vaccine, thirty-six recovered. In nurslings and very young children the initial dose is 0.25 or 0.5 mil; on the second day, 0.33 or 0.5 mil is given; on the third, 0.5 or 1.0 mil, and on subsequent days, 1.0 mil, until fever has subsided and all auscultatory signs have disappeared. In older children or adults, the doses are doubled. Where no improvement follows the fourth injection, the case is probably streptococcic. In such cases, the writer adds to the vaccine a serum prepared from six strains of streptococcus by Sédallian, in doses starting at thirty mils. Undoubted successes were thus obtained in exceedingly grave cases.

Intramuscular Use of Ether in Pertussis.—Abraham Tow (*American Journal of Diseases of Children,* April, 1925) reports that fifty out of sixty-one children suffering from whooping cough were aided by the use of ether intramuscularly. The ages varied from twenty days to seven years. The number of paroxysms was reduced and their severity lessened; the patients slept better; their appetite improved, and vomiting also was lessened. Eleven patients were not aided. In the case of one adult, four injections produced an excellent result.

Seven out of eighty patients had necrotic areas at the site of injection. In this series, a commercial brand of sulphuric ether used ordinarily for anesthesia was taken directly from its container and was injected deep into the gluteal region. One cubic centimetre was given to all patients under one year of age, and doses up to two c.c. to those above that age. The injections were made daily for three to six days and then every other or third day, according to the need of the patient. If there was no improvement after five or six injections, they were discontinued. The point of election for injection was posteriorly about two inches below the middle of the crest of the ilium deep down almost to the bone.

The author concludes that ether intramuscularly is a valuable drug in the treatment of pertussis, but the danger of necrosis must be borne in mind.

Clinical Course of Vaccine Treated Pertussis in Private Practice.—C. A. Aldrich (*American Journal of Diseases of Children,* April, 1925) reports the results of vaccine therapy in a carefully followed series of sixty-five consecutive cases of pertussis and the results of vaccine prophylaxis is seventeen consecutive pertussis contacts seen during the same epidemic. The following conclusions are drawn:

1. As to the merit, patients treated after the onset of symptoms had slightly milder attacks, which terminated somewhat earlier than as outlined in standard textbooks. There were no complications except the usual bronchitis. There is evidence that in some the disease was aborted during the catarrhal stage.

2. As to the prophylactic value, definite evidence is shown that some cases were prevented, although in the absence of controls the percentage cannot be estimated. Only four of the seventeen patients given prophylactic treatment developed pertussis.

3. As to the course of the disease, the average duration was about six weeks, with definite and lasting improvement beginning less than four weeks from the onset. The average patient was up with paroxysms three to four times at night during the height of the disease. The vomiting was of short duration.

4. As to the best time for treatment, the duration of the disease and the length of time before improvement were approximately the same, regardless of the time of treatment, but the patients treated later had slightly severer attacks. The occurrence of several cases in which it appeared that the disease was aborted in the catarrhal stage, however, makes it seem advisable to give treatment as early as possible.

Acute Serous Encephalitis in Children.—Charles L. Brown and Douglas Symmers (*American Journal of Diseases of Children,* February, 1925) report a series of ten cases (of which five were observed by themselves) of acute serous encephalitis, a newly recognized disease of children. The youngest child was twenty-two months of age, the oldest seven years, the average age being less than twenty-eight months. The disease occurred five times in males and five times in females. The condition is of rapid onset and is initiated by such symptoms as irritability, lack of appetite, vomiting or diarrhea or both, and noticeably often by sore throat, the whole followed by elevation of temperature, sometimes to the extent of 105° or 106° F. and by signs referable to derangement of the central nervous system, among them bulbar signs in the form of respiratory irregularities, ptosis, strabismus, nystagmus, papilledema, retraction of the angle of the mouth, muscular twitchings, rigidity of the neck or jaw, hemiplegia, coma, convulsions and death within thirty-six or forty-eight hours or, at the longest, a few days. The cases are separable into two clinical groups, one in which convulsions are associated with one or several of the localizing signs which have just been enumerated; in the second group no such signs are present and the only obvious symptom of derangement of

the central nervous system is to be found in the convulsions. The most striking feature of the convulsions is that they are absolutely uncontrollable by any of the measures commonly employed for this purpose, including the use of such drugs as morphine and chloral.

Anatomically, the disease is characterized by extreme enlargement of the brain, with bulging when the dura is opened. The pia arachnoid is intensely engorged, and splotchlike hemorrhages may be present. The convolutions are flattened extraordinarily, the sulci are obliterated, and the brain is so soft as to give one the sensation of flowing. On section, the substance of the brain is pinkish.

Microscopically, the most constant changes are the hyperemia and edema of the pia arachnoid, engorgement of the bloodvessels of the brain, perivascular and pericellular edema, with or without vacuolation of the ground substance, and acute cloudy swelling of the pyramidal cells. Hemorrhages into the brain are very rare. In places, numerous glia cells are seen, each lying in what appears to be a vacuole, but represents an area of edema. There may be focal collections of a dozen or more cells made up of glia cells, together with lymphocytic and neutrophilic cells. Occasionally, there is proliferation of the endothelial cells of the arterioles. This seems to be a vascular disease attended by the escape of serum rather than of cells; that is to say, that the disease belongs in the same general category with the socalled encephalitis lethargica.

OBSTETRICS

A Sure Early Diagnostic Sign of Extrauterine Pregnancy.—Z. Banki (*Zentralblatt für Gynäkologie,* January 17, 1925) calls attention to an absolute early sign of extrauterine pregnancy, which consists of a sharp pain when the portio or entire uterus is pushed upward toward the symphysis pubis when one or two fingers are introduced into the posterior formix. It is said to be due to an adhesive peritonitis as a result of the oozing of blood into the cul-de-sac of Douglas previous to the rupturing of the tube. When corroborated by the history of the case it may be considered as an absolute sign of extrauterine pregnancy. It is also of value in the differential diagnosis from criminal abortion and appendicitis. It is of no value, however, in the exceptional cases of old adhesions in the cul-de-sac of Douglas even in the presence of an extrauterine pregnancy.

The Use of Mercurochrome in Obstetrics.—H. W. Mayes (*American Journal of Obstetrics and Gynecology,* July, 1925) believes an attempt should be made to sterilize the birth canal before every delivery. An antiseptic in the vagina during labor reduces the chances of infection during that period. In this connection he favors a four per cent. solution of mercurochrome, which is nonirritating. An eight months' clinical study of it showed fewer days of morbidity than when iodine was used. It is particularly adapted for induction of labor and all operative deliveries. It is preferable to iodine in vaginal preparations because it can be applied without an anesthetic, is painless, and entails no risk of irritation or blistering of the skin or mucous membranes of the vagina and rectum. Repeated applications of it can be made during labor and delivery. It seems harmless to the infants, and can be used in large amounts. The skin and mucosæ, though stained, remain soft and pliable. The drug does not coagulate protein, and can be applied to lacerated tissue without injury. In the preparation of parturients on admission, the author, after preliminary cleansing of the vulva with green soap and water, has the external genitalia and introitus of the patient, when she is in labor, painted thoroughly with the mercurochrome solution. The hips are then elevated and one dram of the solution instilled into the vagina with a large medicine dropper to which is attached a piece of catheter four inches long. In preparation for vaginal examination, delivery or induction of labor, the inner sides of the thighs, buttocks, lower abdomen and external genitals are sprayed with the mercurochrome solution and the vaginal outlet and anal region painted with it, whereupon two fingers are inserted in the vagina and one dram of the solution instilled and worked well into the mucosal folds and around the cervix or presenting part. Whenever the field becomes soiled with feces or otherwise, it is cleansed with saline solution and more mercurochrome used. If an hour or more elapses between vaginal examinations or between such an examination and delivery, the preparation is repeated. For induction of labor the patient is put in the Clark position and the bag inserted after the vagina is filled with mercurochrome solution; when the bag is tied, the vagina is again filled with the solution and a small gauze pack inserted. When possible, at least one hour should elapse between the time when mercurochrome is first put into the vagina and the beginning of delivery or any operative interference.

Prevention of Puerperal Morbidity and Mortality.—As the result of an experimental study in clinical obstetrics, Frances Ivens (*British Medical Journal,* March 28, 1925) draws the following conclusions:

1. That latent or preexisting infection, streptococcal, gonorrheal, or coliform, is responsible for a considerable percentage of cases of puerperal sepsis. That the organism may not infrequently be isolated by bacteriological examinations of the urine during pregnancy, especially in cases of streptococcal or coliform infection. That intermittent albuminuria during pregnancy is an indication for a bacteriological examination of the urine, even in the absence of urinary symptoms. That without latent infection uterine inertia is more likely to occur, especially when associated with premature rupture of the membranes. That bacteriological facilities for the examination of discharges during pregnancy, if utilized, will enable suitable precautions to be taken and an appropriate serum to be obtained.

2. That for the prevention of puerperal sepsis patients should be removed from unsuitable surroundings, especially when difficulty is anticipated, and that accommodation should be arranged so that patients may be admitted a day or two before labor is anticipated.

3. That a rigidly aseptic technic is as important as for a surgical operation. The patient should be carefully prepared and the vulva shaved before any vaginal examination is made during or immediately before labor. That well trained midwives can deliver a very high percentage of maternity cases if satisfactory antenatal examination and care have been given by the patient's doctor, and if skilled medical help, and, if necessary, institutional treatment can be obtained when required. Cooperation between midwives and doctors should be aimed at, and maternity homes should be worked in conjunction with hospitals where expert antenatal and obstetrical treatment can be obtained.

4. That with a reliable technic in good surroundings operative measures need not cause puerperal sepsis.

5. That in view of the need for study of the origin and character of the infecting organism in cases of fulminating puerperal fever, such cases should be placed at the earliest possible moment under the care of an obstetrical specialist and bacteriologist with facilities for research on the special type of organism.

Glycosuria of Pregnancy.—John T. Williams (*Boston Medical and Surgical Journal,* January 22, 1925) presents the following observations:

1. Sugar was found in the urine of 13.6 per cent. of five hundred pregnant women at some time during pregnancy.

2. It was found more commonly in primigravidæ than in multigravidæ.

3. In primigravidæ its incidence seemed to increase with the age of the patients. In multigravidæ no difference was observed.

4. It was found more commonly during the second half of pregnancy.

5. The sugar found in the urine during pregnancy is always glucose and not lactose. Lactose, however, is present in the urine of a considerable proportion of nursing women during the period of breast engorgement.

6. The ordinary glycosuria of pregnancy is physiological only and disappears after delivery.

7. The glycosuria of pregnancy is a renal glycosuria not being accompanied by any increase in blood sugar.

8. The physiological glycosuria of pregnancy must be differentiated from diabetes with which it has no connection. This can be done by determination of the blood sugar and by follow up work.

9. The physiological glycosuria of pregnancy is the result of the normal hypertrophy of the posterior lobe of the pituitary body during pregnancy. Increased activity of the posterior pituitary lobe causes glycosuria during pregnancy just as it does when due to pathological causes. After delivery as the pituitary involutes the glycosuria disappears.

ADDITIONAL DAMAGE FOR ALLEGED NEGLIGENCE

In an action for the death and suffering of an infant child, in the delivery of whom the femur of the left leg was broken, the plaintiff claimed that the jury should have been instructed as to the liability of the defendant for the negligence of a doctor who was afterwards called in to attend the child. This claim was based upon the rule of damages recognized in Massachusetts and other cases, that a person injured through the negligence of another may recover of that person such additional damages as result to him from the negligence or want of skill of a physician called in to alleviate or cure the initial harm, if the person injured exercised reasonable care in selecting a competent physician. The jury, however, had found for the defendant substantially that there was no original negligent act or want of the required skill on the part of the defendant in his treatment of the child. The Massachusetts Supreme Judicial Court therefore held, Kos v. Brault, 146 N. E. 16, that there was no issue to which the requested instruction was applicable, and the request therefor was rightly refused.

PROCEDURE IN REVOCATION OF REGISTRATION FOR ASSISTING UNREGISTERED PRACTITIONER

The Supreme Judicial Court of Massachusetts, Davis v. Calderwood, 146 N. E. 708, holds that Gen. Laws, c.112, regulating the practice of medicine in Massachusetts and conferring powers of registration of physicians and of revocation of such registration for cause, the constitutionality of which has been decided or assumed in several prior Massachusetts cases, is valid.

The statute (Gen. Laws, c, 13 § 10) requires a hearing before a public board, at which the practitioner in a proceeding to revoke registration may be represented by counsel and call witnesses, with provision for further hearing in court and for revision and reversal of the finding of the board if justice demands such action. Every constitutional right is held to be protected.

It is held that the notice to be issued to a registered physician of such a hearing is not to be construed with technical strictness. It is to be assumed also that further specifications would be given on proper request in any instance when the subject matter was not fairly set out in the initial notice. Every presumption is to be made in favor of the regularity and fairness of the methods of procedure and of the proposed action of such a board.

It is held that under Gen. Laws c. 112, § 2, assisting an unregistered person in practicing medicine is a sufficient ground for the revocation or cancellation of a registration.

HEARSAY STATEMENTS TO PHYSICIAN AS TO CAUSE OF MALIGNANT GROWTH HELD ADMISSIBLE

The Maryland Court of Appeals holds, Standard Oil Co. of New Jersey v. Mealey, 127 Atl. 850, that hearsay statements of a deceased workman made to his wife and to his physicians that he had fallen and struck his side at a spot where a malignant growth later developed, were properly admitted on the issue whether his death from lympho-sarcoma or leukemia resulted from accidental injury, under Maryland Workmen's Compensation Act, §§ 10, 56.

OPTIC ATROPHY FROM THE ACTION OF ULTRAVIOLET RAYS HELD NOT COMPENSABLE

The Ohio Supreme Court holds, Industrial Commission of Ohio, 146 N. E. 305, that where the action of ultraviolet rays resulting in injury to the optic nerve of a moving picture operator, caused optic atrophy, the condition was not the result of traumatic injury or accident, and therefore was not compensable under Ohio Gen. Code, § 1465-68.

HYSTERONEURASTHENIA FROM ELECTRIC SHOCK HELD COMPENSABLE

In proceedings under the Illinois Workmen's Compensation Act, there was medical expert testimony that while the effects of an electric shock are immediate, hysteroneurasthenia is a common result of such an accident and will disable a man as completely as a physical impediment. The evidence was held to warrant the conclusion that the claimant was suffering from some trouble which incapacitated or partially incapacitated him for physical labor. The Illinois Supreme Court held, Harrisburg Coal Mining Co. v. Industrial Commission, 315 Ill. 377, 146 N. E. 543, that if the accident did not directly produce the effects complained of the shock to claimant's system produced in his mind the conviction that his health and physical vigor were destroyed, resulting in hysteroneurasthenia and incapacity to work, and that he was entitled to an award of compensation for permanent partial disability.

BLOOD POISONING FROM SCRATCHING PIMPLE WITH INFECTED FINGER HELD COMPENSABLE

The New York Court of Appeals holds, Connelly v. Hunt Furniture Co., 240 N. Y. 83, 147 N. E. 366 (by a court divided four to three), reversing 212 App. Div. 225, 207 N. Y. Supp. 695, that the injection of gangrenous matter from a corpse into a cut in the hand of an embalmer's assistant was an accidental injury arising in the course of employment, warranting compensation for his death from blood poisoning when he scratched a pimple on his neck with the infected finger.

DAMAGES FOR FACTURE OF FEMUR IN ACCIDENT

The New Jersey Supreme Court holds, Peters v. United States Stores Corp., 127 Att. 274, that a verdict of $10,000 to a woman, aged 36, injured on the forehead in an automobile accident and by a fracture of the right femur resulting in a shortening of the right leg of one and one-half inches and a permanent impairment of the functions of the leg of 60 per cent. requiring the use of a crutch thirteen months after the accident, was not excessive.

MANDAMUS HELD NOT TO LIE TO COMPEL REINSTATEMENT OF PHYSICIAN WHERE APPEAL LIES FROM REFUSAL TO REINSTATE

The Washington Supreme Court holds, Russell v. Dibble, 231 Pac. 18, that an appeal lies from the refusal of the board of state medical examiners, or the director of licenses, its successor, to reinstate a physician whose license has been revoked, and that such right of appeal is not inadequate, because such delay as would have occurred would not be unreasonable under the circumstances, and upon appeal the court would have full power to go into the merits of the controversy, the statute providing that such matters shall be tried *de novo*, as civil actions are. It is therefore held that in such a case mandamus will not lie to compel reinstatement, since a writ of mandamus will not issue if there is a plain, speedy and adequate remedy by appeal.

LEGACY TO HOSPITAL MERGED WITH ANOTHER

A legacy to a hospital, which before the testator's death was consolidated with another hospital, was held payable to the consolidated corporation. In re Doane's Estate, 208 N. Y. Supp. 320.

Some Aspects of Carcinoma of the Rectum and of Carcinoma in General*

J. RAWSON PENNINGTON, M.D., F.A.C.S.

Chicago

For several years I have been greatly interested in carcinoma in general, as well as in that type involving the rectum and sigmoid, with which I am particularly concerned. Have assisted in the propaganda of Cancer Week, both in my city and state, and have published some essays, notably as regards etiology.

Therefore, prior to a consideration of rectal carcinoma, I propose to review some recent work on etiology and diagnosis, starting with that of Sandes, of Australia. He observes that in many physiological and pathological processes the potassium atom plays an important part. So far as is known it is the only one in the body which gives off electrons similar to radium. Its intimate relationship with calcium and sodium maintains the functional efficiency of protoplasm. It is, as it were, a key to cell life, and the coarse adjustment (of which the hydrogen ion is the fine) in the maintenance of cell function. Further, by reason of its radiations, it is a potent mechanical factor in the energizing of cell constituents so that vital phenomena are produced. In the presence of long continued irritation the reaction of cells to injurious stimuli and the pathological consequences therefrom, Sandes suggests, are largely due to disturbance of their potassium distribution and metabolism, and in certain malignant growths the same cause is at work. It is well known that radiations of different wave lengths are capable of creating and curing inflammatory and malignant conditions. The cell is a reversible engine in this respect, and the potassium and hydrogen ion concentrations the most likely to be affected.

Years ago Mottram, in Lazarus-Barlow's laboratory, showed that the potassium content of the red cells in cancerous patients is considerably higher than in health (1.5:3), while the sodium content shows no change. Moreover, while the sodium content of all carcinoma is about the same, that of potassium in primary growths is higher than in secondary, and of squamous celled tumors higher than of spheroidal celled.

Another physiochemical theory is that of Perrin, of France, which was recently referred to by Magrou: This regards the production of tumors as due to radiation, the dislocations of chromatin accompanying caryokinesis are set up by excessively frequent radiations, the cells act as sounding boards, entering into vibration (i. e., caryokinesis), if they are in the path of light rays of the necessary frequency. This agrees with what we know of the action of radium and of x rays. It may be objected, adds Magrou, that very few individuals are subjected to the action of radium. But, he continues, every living being contains within itself another source of feeble radioactivity—potassium—which, as the experiments of Nègre and others show, is capable of encouraging the development of cancer grafts. Magrou believes if it be demonstrated that this action of potassium depends on its radioactivity, we are authorized to conclude that the genesis of tumors is related to some disturbance of the potassium compounds normally impregnating the tissues.

Barclay, the English radiologist, at the last meeting of the American Medical Association, read a thoughtful paper on the problem of malignancy, which he considered from a purely radiological viewpoint. As a result of experience in three remarkable cases, it occurred to him that perhaps a malignant growth might be originated by a malignant causative disease and these elements might exist concurrently, or the causative disease having started the malignant overgrowth, might die out, leaving the growth to cause death of the patient. There are evidently different types, histologically identical, i. e., radiosensitive and insensitive. Since all tissues can be killed by destructive doses, all growths are classed as radioinsensitive which have the same or greater tolerance than the surrounding structures.

Whenever we see a patient with cachexia, apart from septic absorption, we know that, no matter whether the mass responds or not to x rays, the patient will steadily go down hill, and in the terminal stages the temperature will rise, quite apart from any sepsis. Its presence is often suggested in those malignant diseases of slow growth in which metastases are not attacking vital organs, and it gives one the impression that the ordinary causes of death in these diseases (extension and sepsis) are not only accidental, but that many of these growths are only an incident in an underlying malignant disease. Barclay calls this hypothetical quantity, this essential

*An amplification of an article read before the American Proctologic Society, Atlantic City, May 25, 26, 1925.

Copyright, 1925, by A. R. Elliott Publishing Company.

underlying process, x, and believes it may disappear after originating the growth, and also it may vary in intensity, quite apart from the type of growth it evokes. In the radiosensitive type we may hope for complete success if we can locate and heal the primary focus and its metastases, but if x is still at work, even in a very mild form, we shall fail, for sooner or later recurrences, even if of the radiosensitive type, will come where we cannot detect them, and death follows. In the radioinsensitive type we can do nothing but watch the progress of the growth and its metastases. If we are to find the cause of malignancy we must attempt to determine accurately in which of our cases x is still at work, and find out in what way the blood differs from those where the disease is only locally present, i. e., where x is no longer present. If one might indulge in pure speculation one might accept x as a temporary or permanent blood condition, very slight changes determining whether its action should influence one or another of the different types of cell to cancerous growth. Suppose at the time of this slight blood indisposition there was irritation of, say, the breast cells by some cause, it might stimulate these cells to disordered overgrowth, forming a malignant tumor that would run its fatal course, while the underlying malignant disease, the blood change, entirely disappeared. The patient is operated on and there is a socalled cure. One could imagine the same sequence again after many years, and surely this is more reasonable than to think of malignant cells lying dormant for perhaps twenty years.

But few of the alleged microbic causes of carcinoma deserve mention and one of these is the micrococcus found by Nuzum. I attach some importance to this, not because the discoverer is a fellow townsman, but because my friend the late A. J. Ochsner was firmly convinced to the day of his untimely death that the true cause had been found. His opinion is all the more weighty since in addition to his enormous clinical experience, Dr. Ochsner was a master of microscopic technic in his early career, and for many years made it an invariable practice every Sunday morning to inspect the slides made from the tissues removed at operation the previous week.

In 1921 Young, of Edinburgh, announced the discovery of the causal organism, and a year ago furnished some further investigations. According to these, the organism in question can "grow independently in any one of the following forms: a large yeastlike body of varying sizes, cocci of differing size, bacilli and threads of a granular or uniform character and of varying thickness, minute granules and an amorphous material, which appears as regular globules or as irregular masses of greatly differing staining capacity. . . . The original fungus is capable of devolving into all the other forms, and during its metamorphosis it practically invariably first becomes transformed into a homogeneous structureless material or plasm in which the new elements appear as minute granules. The plasm is thus totipotential; it can generate yeast, coccus, bacillus or thread." (For the peace of mind of future medical students it is to be hoped these findings which overthrow all previous knowledge of bacteriology are incorrect.)

A few weeks ago the papers were full of cablegrams from England that the "cause of cancer" had finally been tracked to its lair. Even allowing for the notorious inaccuracy of newspapers when reporting any scientific discovery, it seemed as though something of importance had transpired. The issue of the London *Lancet* with the articles of Gye and Barnard, is just at hand, and their preliminary report therein contained holds out some promise, it is true. However, the neoplasms investigated were the Rous chicken sarcomas, and while at first these were not looked on as true malignant tumors as understood in human pathology, I believe they are so regarded at present, though with a few dissenting voices. Possibly the technical methods described will put us on the right track, and further reports will be impatiently looked for.

Long since Virchow stressed chronic irritation as a potent cause, and as one phase of the precancerous state seems to be growing more and more in favor.

W. J. Mayo last fall, in one of his many masterly addresses, stated: "I have never observed a case of cancer in which there had not been some preexisting instability of the tissues, and a longcontinued irritation. It would seem as if the longsuffering tissues respond to the chronic insult of the injury by supplying cells less and less mature, until finally the tissues reach a stage in which there is uncontrolled production of unsound cells, too immature to heal the breach of continuity, or to furnish protection to normally protected tissues."

Speaking of irritation, a case reported by McGraw and Schrankel, seems conclusive. They give the details of the case of a woman, aged forty-one, who had the left leg amputated in midthigh at the age of eight, on account of an injury. At twenty-three she fractured the patella, which was repaired by open operation. Since then she had used two crutches, holding them close to the body so that the mammæ were compressed toward the midline. As a result hard masses developed in both mammæ, and biopsy revealed carcinoma.

Coplin refers to an interesting example of growth apparently caused by two entirely distinct irritants in a röntgenologist who was a heavy smoker. In addition to lesions on the fingers, a labial cancer developed; the latter was excised about six weeks after it appeared and never recurred. The x ray growth finally caused death some ten years later.

Another recent and striking instance is narrated by M. Peraire (Paris) who said he had had occasion to perform total hysterectomy for fibroma complicated with epithelioma on a patient, on whom he had operated twenty-one years previously for salpingooöphoritis of right side with appendicitis. Examination of the specimen showed the carcinoma had started at the old cicatrix on the right ovarian pedicle, and then followed the uterine mucosa and the vagina.

Borrel (in 1905) showed that many mice with cancer were infested with cysticerci of a tapeworm found in the cat, and a year later surmised that the cysticerci might carry a cancerous virus with them; however, he soon abandoned this latter. It was not long (1907) before Fiebiger (in Denmark) found a similar state of affairs: Eggs of a nematode worm being eaten by cockroaches, and these in turn eaten by rats, develop in the stomach of the rats. As a result there are enormous epithelial proliferations, especially

about the cardia; polypi form and hang free in the stomach. In some, not all animals, malignant tumors ensue with metastases. It is interesting to note that, according to Joyeux, the causal worm dies early, but the irritation set up gives rise to continuous tumor growth.

Further corroboration was afforded by Sambon a year or so ago, who found in Italy the same vicious circle of cockroaches and mealworms—rats and mice. In some districts of that country he found cancer in humans very common, and the same parasitic worm as in Denmark present in sheep, cattle, goats and hogs, involving the esophagus and cardia as it did in human beings. Moreover, during a tour of Iceland he found cancer had never been heard of in the inhabitants of a remote and desertlike district, nor were there rats, mice or cockroaches.

The lesions produced in the bladder and rectum by another parasitic worm (Bilharzia) have been known for many years, but of late it has been discovered that carcinoma may develop ultimately on these lesions; Ferguson especially has emphasized this. In South Africa also, Pirie examining thirty-six primary carcinomas of the liver in the native blacks, found they were a sequel of cirrhosis. Moreover, in ten cases the cirrhosis was clearly superposed on bilharzial lesions, and probably was also in the remainder.

The long series of successful animal experiments in which carcinoma is produced by irritation of the skin from painting on tar, and other materials, was begun by Yamagiwa and Ichikawa nearly a decade ago. In his late article, the latter states he now obtains thirty per cent. of successes, and nearly two per cent. of metastases, and concludes that simple chemical and physical irritation if repeated renders the normal epithelial cell cancerous, without interposition of other causes. Finally, that he is a firm partisan of Virchow's theory.

Speaking at the International Cancer Conference at Strasburg (1923) Murray, of the Imperial Cancer Research Fund, observed that the extent of the surfaces to which irritants, tar, etc., were applied had no influence on the rapidity of production of cancer and the percentage of successes. The frequency of the applications and the intensity of the irritation, on the contrary, played a great part. The successful result is due, in part, to irritations of medium intensity and not too close together. This accounts for the fact that cancer is rare among workers in chromic acid, though they may have ulcers from the acid (chrome holes), and similar industries. The resistance of the animals varies greatly, ranging from three to eighteen months, before success is had, while some individuals are utterly refractory.

A fortnight prior to Gye's communication, Kennaway furnished the account of some experiments on cancer producing substances at the Research Institute of the London Cancer Hospital. He was able to produce tarlike compounds which turned out to be particularly successful in causing epithelial growths, yet such compounds were comparatively simple, being made up of carbon and hydrogen only. Attempts to produce similar substances from previously living tissues were again successful—a socalled tar from yeast, as well as a product obtained by distillation of human skin had this cancer producing property.

A petroleum which produced no tumors of any kind in mice in a prolonged experiment showed very active cancer producing properties after exposure to a temperature of 880° C. The cancer producing substance in coal tar is formed only in small amounts under 450° C.; at 560° C. it appears in much larger quantities, and this increase continues at a slower rate up to 1250° C.

There are many other examples of irritation giving rise to carcinoma: The famous kangri burns, of Kashmir, the chewing of betel nut by their neighbors, and—nearer home—lingual and buccal growths from jagged teeth or illfitting dentures, etc., but limitations of space forbid anything but brief mention. An essential in all these cases is that the irritation be long continued. Thus, Wyeth alludes to a case where radical measures were indicated in an epithelioma, some forty-seven years after the original injury; in the meantime there had been an interminable succession of trauma, infections and ulcerations. This long continued irritation, of course, may account for the fact that carcinoma is more frequent in the aged.

One disconcerting feature of the experimental irritations was, I believe, first noted by the late E. F. Bashford, of London: instead of carcinoma developing, the resulting tumor was a sarcoma. Similar experience has been had since in other laboratories, and is looked on by some writers as showing sarcoma and carcinoma are due to the same cause. Assuming this to be correct, it seems strange the clinical behavior of the two neoplasms should differ so—sarcoma often arising from a single trauma, spread by the bloodvessels, generally attacking younger subjects, and in structure showing little resemblance to the epithelial growths.

All this has led me far afield from my habitual hunting ground—the rectum and pelvic colon, but is introduced preparatory to subsequent remarks on prophylaxis.

Some authors lay stress on hemorrhoids as an etiological factor in rectal carcinoma. Thus Rosser writes: "One cannot but be impressed by the number with a history of piles for years before the malignancy appeared." The proportion of cases of carcinoma with hemorrhoids varies from 3.75 per cent. in Kocher's clinic according to DuPan, to thirty-eight per cent. (Zinner). No doubt some—maybe many—of these were symptomatic from disturbed circulation due to the tumor. Since practically every adult has hemorrhoids at some time during life, if they have any causal influence, it seems to me the ravages of carcinoma—extensive as they are—would be materially increased. Anyway, carcinoma usually occurs above the zone affected by hemorrhoids. In my book I refer to 1,828 instances, seventy per cent. of which were in the ampulla, and the figures I have collected since show the same preponderance.

The question of heredity comes up in connection with etiology. Several years ago Levin studied a number of families for several generations, analyzing the family incidence from the viewpoint of Mendel's laws of genetics. As a result of these investigations he concluded the frequency of carcinoma in the families studied was no greater than that of the populace at large.

On the other hand, early this year Mummery gave the history of three families, the members of which

had had adenomatosis for several generations, and a large proportion died of cancer of the rectum, and that at a comparatively early age; e. g., in one instance seven between twenty-seven and fifty-four years.

DIAGNOSIS

So late as August 16th last Drummond writes: "Intestinal obstruction, acute, subacute or chronic, the discovery of a tumor, and bleeding from the bowel, are the chief indications of intestinal cancer." A good example of English conservatism! What is wanted is not a recital of such terminal symptoms when even the patients themselves suspect they have cancer, but some means of detecting the presence of cancer in the interior of the organism in the early stages; unfortunately this is still lacking.

Quite recently Fry, of the Research Institute of the London Cancer Hospital, described a method of serum diagnosis: The antigen is prepared from carcinoma of the mammæ, and composed of the alcohol soluble constituents. This alcoholic extract, strengthened by cholesterol, is standardized and added to four dilutions of the inactivated serum to be tested. After incubation, a preliminary reading is taken at the end of three hours, the end result being determined after twenty-four hours at room temperature; if positive, flocculi appear in the tubes. A series of five hundred malignant and nonmalignant conditions were tested, and seventy-five per cent. of correct results obtained; in the cancer cases positive results were had in seventy-one per cent. and in the noncancerous seventy-eight per cent. of negative results; while the controls from healthy subjects were negative in all but one. The antigen, it is said, is very similar to that used for the Wassermann reaction, but syphilitic serum does not seem sensitive to Fry's test. In 233 cases of malignant disease, twenty-one positive Wassermanns were obtained, in contrast with the 170 positive flocculations. Of 253 Wassermanns on the controls, eighteen were positive, but there were only seven positive flocculations.

Further investigations may corroborate the value of this reaction, but equally glowing claims were made for the methods introduced by Abderhalden, Ascoli, *et al.* In his essay on serological diagnosis in cancer, Lavedan describes a total of three types and sixteen varieties each with several subvarieties, and concludes: "Early serum diagnosis of cancer remains to be discovered." While written just previous to Fry's article, Lavedan has great hopes apparently for Botelho's method, which Fry states: "has been shown by me to have little diagnostic value," and so we must wait hopefully it seems.

In connection with diagnosis I wish to refer to the question of age: We instinctively, as it were, look on carcinoma as an appanage of old age, but evidence is rapidly accumulating that this condition may affect comparatively young subjects. In my treatise, I tabulate some early ages as follows: eleven years, three;; twelve years, five; thirteen years, three; fourteen years, three; fifteen years, four; sixteen years, two; seventeen years, six. Since then Phifer, placing a case in a man, aged nineteen, on record, collected forty-eight cases in the rectum and pelvic colon in young subjects—six to ten years, one; eleven to fifteen, twenty-two, and sixteen to twenty, twenty-five. Applehaus also recounts one in a man, of twenty-five. This early age incidence holds good for other organs as well, e. g., uterus, at twenty years (Heusinkveld); liver, at thirteen years (Johnson), and others.

As regards diagnosis of rectal cancer in general, recent case from Homans (Boston) can be duplicated in the experience of all of us: A man, less than fifty, appearing in robust health, for past two months had discomfort pretty continuously, moderate dull ache in lower abdomen, and a sense of a lump in the epigastrium. His troubles were neither brought on by nor relieved by eating. His bowels, previously regular, had become moderately constipated so he found himself taking cathartics. Physicians consulted several times had reassured him as to the seriousness of his condition. The abdomen was soft, easily palpated and not distended. No tumor could be felt and rectal examination was negative. However, a barium enema disclosed a narrowing and irregularity in the rectosigmoid region, and this was confirmed by proctoscopic examination. Later, a typical cancer was resected.

In eight cases narrated by Küttner, the diagnosis was obscured by the presence of tuberculosis. While Rokitansky, the famous Vienna pathologist, asserted long ago that tuberculosis and cancer would not be found in the same subject, it has since been found this statement is too sweeping. Christèn met with a family history of tuberculosis in 25.5 per cent. of his cases of rectal cancer. On five occasions Kuttner found tuberculosis of lungs masked the bowel tumor, and in the others the systemic condition (weakness, anemia, and other conditions) had been atributed to tuberculosis and no examination made of rectum.

I dismiss considerations of diagnosis with the statement that about half of the subjects with cancer of the alimentary canal, seen by Lenoir in Paris, had excess of blood sugar. This may lead to some practical application.

Taking up operability next, in the Continental clinics this used to range from nineteen per cent. (Boas) to over four times this, or eighty per cent. (Von Bergmann). In Great Britain Miles estimated it at seventy-five per cent. A few years ago Back questioned a number of his colleagues in London, as to their estimates of operability—the extremes were twenty and forty per cent., Back's own estimate is under thirty. In this country our president a year ago stated sixty-one per cent. of 110 cases were operable; it is interesting to note that even of the anorectal growths eight out of fourteen were inoperable, and—as we should expect—nine of the eleven rectosigmoid ones.

With the improvements in technic of recent years, the percentage of operability has materially increased, e. g., at the Mayo Clinic it rose from fifty-one to 71.8 per cent., while the operative mortality decreased from 17.7 to 12.5. This increase of operability is in great part due to interventions even though the contiguous structures be involved—prostate, uterus, vagina, small intestine, etc.

Again, enlarged lymph nodes were a formal contraindication not long ago. A few years back McVay of the Mayo Clinic studied one hundred rectal cancers removed by operation. Over six nodes from each specimen were dissected out, and carefully examined. As a result he decided "the size of the growth cannot be relied on as an accurate index of the probable

lymphatic involvement. The growths without involvement tend to grow into the lumen, those with slight involvement to spread by direct extension and are slow growing. Carcinoma of the rectum, with extensive glandular involvement, tends to metastasize early. Lastly, systematic microscopic examination of all regional nodes in carcinoma of rectum appears, as it does in stomach, to be the best method of accurate prognosis."

It has been shown, principally at the Mayo Clinic, that the enlarged nodes are often merely inflammatory and not cancerous.

Paterson is another example of British conservatism: In his discussion of mammary cancer, he remarked that the proportion of five year cures appears to be the same about as twenty-five years back, when the axilla was not cleared out as a routine, but only when evident the nodes were affected. He believes, as well, that nothing is gained by removing the adjacent nodes with the primary tumor. They are a protective barrier to the spread of cancer cells, and may be removed later with much greater safety.

At Rochester, Broders has formulated an "index of malignancy" which while based on the squamous celled variety, may be available for the cylindrical celled growths which mostly interest us as proctologists. Taking 1,628 specimens he divided them into four groups representing grades of cell maturity: Grade 1, tumors in which the majority (seventy-five per cent.) were differentiated, and thirty-five per cent. undifferentiated or embryonic. Grade 2, cancers where the two types were about equal; Grade 3, in which only twenty-five per cent. showed differentiation, and Grade 4, in which none of the cells approached normal. The end results of operation were then looked up, and it was found good results were obtained in Grade 1 in ninety-two per cent., in Grade 2 in sixty-two per cent., in Grade 3 in twenty-five per cent., and in Grade 4 in only ten per cent. This grading was confirmed in a larger series.

As regards end results long survivals were possible even after the crude methods of the eighties and nineties of the last century. Boeckel, twelve years; Czerny, sixteen years, twenty-four and a half years; Bull, twenty years. The late C. T. Dent, of London, operated November 2, 1882, on a man of fifty-two, by the old fashioned perineal route. The nodes were removed from the ischiorectal fossa, the bowel could not be brought down, but the anus was preserved and good control persisted for solid and partial for liquid feces. Readmitted on January 29, 1920, with evident metastases in liver from which he died in three months.

I have gone into this subject at considerable length in my treatise, so shall only add some of the statistics which have appeared since taking them in chronological order: In Paris, Demarest had 43.4 per cent. of satisfactory results by perineal extirpation after removal of coccyx, though the series was small. Jones and McKittrick state that while the pathologist found no involvement of the perirectal tissues or nodes in sixty-eight per cent. of the specimens removed by them, yet all but 11.3 per cent. of the patients were dead in five years, whether metastases were met with outside bowel or not. Of the subjects dying within three years, ninety-two per cent. had involvement of regional nodes, liver or perirectal tissues when operated on; on the other hand, twenty-three per cent. of those with metastases solely in the regional nodes or the perirectal tissues lived three years or over. Lecène recording survivals of ten, twelve, fourteen and a half and fifteen years, respectively, after the combined method, stated he has never had a ten year survival after the perineal or after the Kraske operations. In his address already quoted, Mayo remarked that at the Clinic, when the cancer had not extended beyond the primary focus, over seventy per cent. of patients are cured, but when beyond such focus, only nineteen per cent.

Küttner gives an account of an enormous number (eight hundred) of conservative sacral operations: About one third with three year cures, and about one quarter with five year; complete continence in 52.9 per cent., almost so in 17.6 per cent. Quite recently Gabriel has given the results in 143 perineal operations by Lockhart-Mummery: The operative mortality was 15.4; some forty-four deaths later (eighty per cent. within three years). Of the remainder thirteen could be traced, so sixty-four are alive, five with evident recurrence. In the remaining fifty-nine, the survivals have been thirteen years, one; ten years, one; nine years, one; over eight years, two; and five to eight years, nine. The functional results in most instances extremely good.

On some occasions the prospective end results are vitiated by the fact that there are multiple growths in the bowel, and the lower one only may be discovered and attacked. Details of five cases of this nature have been published by Miller, and may be due either to multiple primary foci, or to implantation from the higher mass to site below in the intestinal canal.

So much for the end results of operative treatment. I have been interested lately in reading of the natural duration of cancer, on which two articles have appeared in England—one last summer, the other early this year. In my work I refer to the mean survival of inoperable cancer in Kocher's clinic as being twelve months from the first symptom, and to seventy-one of Cripps's cases with extremes of three and thirty-six months, and an average of 7.8. The first of these English articles is by Lazarus-Barlow of the Middlesex Hospital, which you remember has had a cancer department since 1792. He analyzed the cases for forty years, and while he takes up the cervix, mamma, and so on, of course we are only interested at present in the rectum: No cases in which other than palliative operations (colostomy) were performed are included. He found 345 instances—172 males with extremes of three and eighty-six months, and an average of 20.4; while in 173 females, three and 122 months, and the average 25.9.

The other paper is by Wyard of the Cancer Hospital, and deals with 450 cases over a lesser interval (twenty-four years). The sexes are not divided, and the extremes were three and 372 months, with means about the same as in Barlow's cases, or twenty-nine months. An interesting feature is pointed out by Wyard, and that is colostomy did not prolong life, the duration is exactly the same in patients after this operation and in others without operation.

Poor diagnoses are not always responsible for the low per cent. of operability. As far back as 1911 Wainwright gave some findings of the Pennsylvania

Cancer Commission: In 210 individuals with superficial cancer in sixteen different locations (including 102 of mamma) thirty-nine per cent. showed precancerous chronic irritation, the average time after the first cancerous symptoms before advice was sought was eighteen months, and the average time between first consultation and operation thirteen months. Of 188 subjects with deep seated cancers, forty-six per cent. gave evidence of precancerous chronic irritation. The average time lost after first symptom was fourteen months, and twelve more before operation.

In 1920 Simmons and Daland investigated 519 cancers at the Massachusetts General Hospital as to the reason for delay, among them forty-four of rectum. Delay to consultation, 8.4 months; delay before operation was advised, 5.3 months, and 0.7 months more before operation was done. Last year they published results in 339 more subjects—taking all sites the average duration of delay until first consultation was 4.6 months, and from first consultation to operation advised, 2.9 months. It will be seen the delays were less in Simmons and Daland's first series than in Wainwright's, while in the next series it was still less.

Concerning radium therapy: A year or so back Howard Kelly gave his results for the previous decade. 1. In cases treated with radium alone, actual cures 8.5 per cent., with palliation in 69.5 per cent., about half of the latter living over eighteen months. 2. The group with colostomy plus radium gave the fewest cures (6.3 per cent.) but most palliations (68.7 per cent.); moreover, 45.5 per cent. of palliations lived eighteen months or more. 3. Radical surgery plus radium, here the percentage of well subjects was highest (17.5 per cent.) over half were improved; and most of these again, lived eighteen months or over. In this group when admitted 8.6 per cent. were recurrent or hopeless, 27.5 per cent. recurrent and extensive.

Experience elsewhere seems less favorable: At the London Radium Institute, e. g., Pinch states they believe the results of the combined operation far exceed anything to be expected from radium. Lecène had but mediocre results, though he agrees it may be of use in delaying the course of inoperable tumors. In some instances Küttner saw remarkable benefits from radium and x rays, others were unchanged, some improved for a time only, in still others the course seemed accelerated.

The results at the Memorial Hospital (New York) were elaborated by Quick a short time ago: In the four previous years some 160 cases had been treated. A large number were benefited for one to three years, and then succumbed to the disease or to intercurrent affections. Some were in such good condition definitive cure was hoped for. In a few instances the palliation was such that the subjects were able to continue their occupations, though periodical examinations showed the tumor was still present. The oldest cures were of four years' standing, and with marked fibrous stricture due to insufficient screening. On many occasions the condition improved for a time, then metastases soon appeared. He points out that it is useless to subject individuals with such metastases to radiation. Exploratory laparotomy is justified, if tumor is too extensive, useless radiation will be avoided. And, if localized, laparotomy often enables emanation tubes to be inserted in the growth itself.

In the recently issued Fasciculus XIV of the *New Treatise on Medicine,* Bensaude, the Parisian gastroenterologist, states radium is formally contraindicated where there are metastases, for radium excites cancer cells when the primary focus is at a distance. In many instances, he continues, it seems to have neither benefitted nor acted injuriously; though he had rare cases where the action was beneficial. In two others, the combination with x rays produced remarkable effects, though too recently to tell whether permanent or not.

At the Mayo Clinic, according to Bowing (in the last number of *Radiology*) from June, 1919, to June, 1924, some forty-three cancers of rectum were resected, in which radium alone or combined with x rays had been applied before operation; in thirty-five a short time after permanent colostomy. Of these thirty-three could be traced, fifteen dead, and of the survivors, ten are alive, three years after the first application of radium, six between two and three years and two less than a year. He decides the best results are possible only by a sufficient interval between the first radium application and the operation, for all the important effects on the tissues to have subsided, and such time is to be estimated in weeks rather than days.

Two years ago MM. Pauchet and Buquet stated they had applied radium and six weeks later did the perineal operation. "The cancer was not cured." It seems unreasonable even granting the alleged thaumaturgic properties of radium to expect cure in a little over a month.

Finally as regards prevention: In my article in the forthcoming Chicago issue of the *Surgical Clinics of North America,* I use a Hibernicism to the effect that the time to prevent fistula is before you get it, and the same holds true for cancer. How? First, by keeping a vigilant watch over the rectum. How? By repeated systematic examinations. Second, by the removal of all pathological conditions liable to provoke cancer. When? As soon as recognized. How? By that operative technic which will result in the least scar tissue.

There is no use in trying to save a "house on fire" when it is completely enveloped in flames, and the smoke coming out of doors and windows. So it is with cancer of the rectum with the mass practically obstructing it, and the symptoms of ulceration—bleeding, pain, diarrhea, etc.—after the whole system is permeated with its poison. The rectum is one of the most important organs in the body, more so than an eye, ear, kidney, testis or ovary. Should one of these be lost there is still its mate to subserve the purpose of the economy, not so when the terminal bowel is destroyed.

Since 1908 I have iterated and reiterated my suggestion (made at the meeting of our society that year) that every person who has reached the socalled cancer age should be examined at regular intervals for evidence of commencing carcinoma; not necessarily in the rectum alone, but in the female, e. g., of the uterus and mamma as well. Neither patient nor practitioner should allow their interest in these periodic examinations to slacken. At that time I referred to the case of Powers, of Denver, in which such

examinations were made at regular intervals after excision of a mammary cancer, and eighteen years elapsed before the search was rewarded by discovery of a recurrence in the scar.

A much longer period before recurrence is placed on record by Steward (London) early this year. A woman of eighty-one was operated on thirty-one years ago by the late Sir Henry Butlin; he was a celebrated surgeon of his day, with a work on *Diseases of the Tongue* in which he laid stress on cancer, and was the sponsor of the *Unicellula cancri* theory of malignant growth, so probably the intervention was thoroughly done. A few months before seen by Steward after over thirty years of apparent good health, three small nodules were discovered by her medical attendant in the immediate vicinity of the scar, and grew slowly. For two months there were also enlarged veins over chest on same side with some breathlessness and pain. The nodules were hard, each about a half inch wide, dull on percussion. Death in a few hours. Steward believes this to be recurrence in skin and mediastinum; this seems probable, though in such a long interval there may have been independent foci.

Last fall, Bloodgood, of Johns Hopkins, referred to educational efforts especially about cancer of the mammary gland: The records in the Laboratory of Surgical Pathology were divided into decades—the first from 1890-1900, the fourth starting with 1920. The per cent. of inoperable cases has decreased steadily, and is most marked after 1915. The improvement in operability in all regions is greater than the improvement in the per cent. of five year cures. He feels quite confident that in the breast, lip, tongue, skin, the per cent. of permanent cures will show a great increase since 1919, but there is no evidence of this improvement in the gallbladder, stomach, rectum or colon.

From February 17 to 24, 1924, a campaign was carried on in Detroit during Cancer Week and the results are tabulated by Salzstein: Over one thousand persons applied for examination at the hospitals during that period. Of 874 records turned in, it appears that forty-two cancers were found, or 4.8 per cent. of entire number. These figures include only cases where the existence of the tumor was unsuspected, or improper or inadequate treatment advised or given. Of the forty-two cases it seems passing strange that sixteen (nearly half) were in the mammæ, none were discovered in rectum. While of seventy-five precancerous conditions, twenty-three again were benign tumors of breast; a polypus was the affection met with in the rectum.

At first sight Salzstein's figures do not seem to substantiate my advice for repeated systematic examinations, but some six hundred years before Christ, a humpbacked Greek, named Æsop, among other wise sayings wrote that "One swallow does not make a summer." Moreover, if the examinations are repeated often enough in the same series of patients, we may be sure cancers of the lower bowel will be discovered, and that early in some instances. It may be that a good proportion of the patients examined were under the typical "cancer age." It is notorious that polypi are often precursors of malignant disease, and if nothing else was found in the 874 persons, it seems to me the search was well worth while.

This campaign must not be allowed to slow up. In the last issue of the *Illinois Health News,* published by the State Department of Health, we read that in 1902 cancer was seventh in the order of frequency of causes of death. In 1923 it stood third, being exceeded only by cardiac diseases and pneumonia.

Dyspepsias from the Ileocecal Region*

RALPH R. MOOLTEN, M.D.

New York

Dyspepsia has probably a greater numerical occurrence than any other single symptom. It has a multiplicity of productive causes ranging from the slightest dietary indiscretion to the severest organic disease. An analysis of the more persistent cases reveals the significant fact that intrinsic disease of the stomach is an etiological factor of quite minor importance and relative infrequency. In only about twenty per cent. of cases presenting the symptoms of indigestion and dyspepsia is there disease of the stomach; in forty per cent. the lesion is not in the stomach, but elsewhere within the abdomen; and in the remaining forty per cent., the pathology is not within the abdominal cavity.

In the first group (intrinsic stomach disease) the most prominent conditions productive of indigestion are: peptic ulcer, malignancy, and errors in gastric chemistry.

In the second group (extragastric but intraabdominal disease) the commonest causes are a pathological condition of the gallbladder and of the appendix regions. Anatomical abnormalities of the female generative tract and pelvic inflammatory disease may also be placed in this group. More especially, disease of the ovary is frequently the productive cause of indigestion. Not uncommonly, severe nausea and vomiting occur concomitantly with the menstrual epoch.

The third group (extraabdominal conditions) contains, as productive causes of dyspepsia, tuberculosis, cardiac disease, nephritis and the neurotic state.

Therefore, of a hundred cases of dyspepsia, in only twenty will there be a pathological condition that is directly responsible for the gastric symptomatology.

Cabot makes a clinical distinction between regular

*From the Surgical Service of Professor Charles Gordon Heyd, New York Post-Graduate Hospital. Read before the Surgical Conference, New York Post-Graduate Hospital, March 26, 1925.

and irregular dyspepsia, and draws an inferential conclusion as to the nature of the pathology from the clinical picture. The regular dyspepsia obtains where the pathological condition is intrinsically gastric. The irregular dyspepsia is that of reflex production.

Regular dyspepsia is characterized by an unaltering repetition of a syndrome typical for the patient. The chronological occurrence of pain and distress, in relationship to the ingestion of food, is of clocklike precision. Distress always follows certain definite articles of food and relief is occasioned by the same measures.

Irregular indigestion is characterized by extreme variability. Foods which may at times cause severe distress may, at other times, be eaten with relish, unassociated with untoward symptoms; and there is lacking the periodicity of the onset of symptoms.

The ileocecal region is an area that commands attention because of certain anatomical and physiological facts peculiar to itself and in its linking up, in intimate relationship, with the rest of the digestive apparatus. Tracing the alimentary tract from the pharynx to the anal sphincter, there are certain definite points of normal stasis that indicate some change in functional activity and chemistry. The two most important points, or, rather, the two points that mark the most extreme changes, are at the pyloric sphincter and at the ileocecal valve.

The stomach concerns itself with digestion; the small intestine, with the completion of digestion and absorption; the large intestine, with the completion of absorption and evacuation.

Chemically, the normal medium of the stomach is acid. Beyond the pyloric sphincter the medium is alkaline and the ileocecal valve denotes a point of change from an alkaline to an acid medium.

The cecum, moreover, represents a site of maximum fluidity of intestinal content, predominance of lymphoid tissue and maximum bacterial activity.

A study of the lymphatics of the area demonstrates that there are two chains of farreaching importance. One connects the cecum and the right kidney. Remembering the cecum to be the point of maximum bacterial activity the predominance of right sided pyelitis and bacilluria is accounted for. The other chain runs from the appendix region to the gallbladder. Sudler has demonstrated that there is no barrier between the intrahepatic and extrahepatic lymphatics, but that there is an unobstructed lymphatic passage between the gallbladder and the liver. From this point the lymphatics pass down to the pancreas, an organ which Deaver likens to a lymph node at the terminal point of a lymphatic chain. Therefore the lymphatic system would seem to be the connecting link in infections of the appendix, liver and gallbladder and pancreas.

The terminal ileum is separated from the cecum by a competent valve that has a direct functional association, through nerve connection, with the pyloric sphincter. Some physiologists hold that the ileocecal valve is in fact a sphincter itself. In man, it plays the rôle of a sphincter; in cats and dogs, it bears a close anatomical resemblance to a sphincter. For our consideration, it is interesting to note that these two important barriers, the pyloric sphincter and the ileocecal valve, work in a definite relationship to each other. The ingestion of a glass of water, that would close the pyloric sphincter, will also cause a relaxation of the ileocecal valve. Only at the time that the pyloric sphincter is closed can ileal contents pass into the cecum. This is an anatomicophysiological phenomenon that can find its inception at either point. In other words, if the pyloric sphincter can control the status of the ileocecal valve, so can the ileocecal valve control the status of the pyloric sphincter.

In a nicely organized and well functioning gastrointestinal tract, this synchronism of relaxation and closure takes place as a part of normal activity and produces no noticeable effect upon the patient. When, however, the pyloric sphincter takes hold outside of the normal digestive cycle, there follows an interruption of the motor expression of the stomach, and the patient is then made to feel distress.

A peristaltic impulse does not pass from one end of the digestive tract to the other without guidance along its course. There are eight points of specialized nervous tissue along the tract which Keith describes as nodal points, and which closely resemble the nodal tissues of the heart. Four of these nodal points have been definitely demonstrated, and four are surmised with reasonable certainty. They are, 1, at the junction of the pharynx and esophagus; 2, at the cardiac orifice; 3, just beyond the pylorus near the ampulla of Vater; 4, at the duodenojejunal flexure; 5, the ileocecal sphincter; 6, about the midpoint of the transverse colon; 7, the junction of the sigmoid and rectum; and 8, within the anal ring.

At this point it would be well to recall to mind a fundamental conception of the gastrointestinal tract that will serve to explain many of the symptomatic vagaries of which it is capable. I refer to what was called by Bayliss the "law of the intestine," which states that stimulation of any part of the intestine leads to contraction above and relaxation below. This is an expression of Nature's effort to remove an offending object by exaggerated function—hypermotility, hypersecretion and hypertonicity. Violation of this law causes aberrant activity which produces subjective symptoms. For example, stimulation of the pylorus causes closure of the ileocecal valve; and irritation of the cecum causes spasm of the pylorus. And here we see the rôle of the appendix in the production of pylorospasm, with its consequent gastric symptomatology. The presence of infection in an active state is not necessary to produce cecal irritation. A competent productive cause can be an old fibrotic appendix with its attendant adhesions; a long appendix that tugs at its mesentery; a kink in the mesentery itself, or perityphlitic adhesions—monuments to many repeated attacks of appendicitis of mild character.

In a strict sense the term appendicitis should be used to define inflammations of the vermiform appendix. It has, however, obtained a broader clinical significance, embracing various inflammatory affections of the right iliac fossa with which inflammation of the appendix is associated as a more or less important factor. Formerly the term typhlitis was much in use and was based upon the idea that inflammations of the region designated, originated in the cecum and head of the colon and spread from these structures to the surrounding tissues. Modern investigations have shown that in the great majority of instances typhlitis and perityphlitis have their origin in primary

appendicitis, and for practical purposes, these cases should be dealt with as cases of appendicitis.

Notwithstanding the fact that various surgical writers have denied the existence of primary localized inflammations of the cecum without appendicitis, there is abundant evidence, as shown by MacWilliams, that such a condition can exist, independent of tuberculosis, malignancy and such causes; and that when the condition does occur, the etiological factor is ordinarily fecal stasis in the cecum.

After the element of infection has ceased to operate, or where the element of infection is too mild to command surgical consideration on its own merits, we still find the appendix often to blame for trouble that it reflexly causes through the medium of a neuromuscular complex. This is the type of appendicitis that resembles the ulcer syndrome. Everybody who does more than an occasional operation has had the experience of demonstrating, on laparotomy, an ulcer to be nonexistent in a patient who presents all the clinical manifestations of having had one. Moynihan's dictum that the pathology for most peptic ulcers is found in the right lower quadrant cannot be too often repeated.

In conclusion, it may be stated that many cases of irregular indigestion, where the stomach, duodenum and biliary apparatus can be vindicated, will be cured by an appendectomy, however innocent the right quadrant may appear to be.

Pernicious Anemia*

Report No. 2

LEONARD E. CROFT, M.D.

Los Angeles, Calif.

Continuing the subject of pernicious anemia from eight months ago (1), it can be stated in reference to Case II of that series (No. 6081), that the patient improved sufficiently to return, at his own request, to his home, four months after he was seen at the clinic. How long his arrest will hold good we do not know. It is our intention to follow the progress of these men.

Case III of that series (No. 5814), the patient is present. When the patient was last presented his red blood count was 2,300,000; his hemoglobin was 80 per cent.; color index 1.7 plus. His remission held until about February 2, 1925, when his hemoglobin registered 45 per cent., and his red blood count was slightly over 2,000,000. Seven days later his hemoglobin was 35 per cent, and red blood cells 1,584,000. He received several transfusions of 500 c. c. each, the last one recorded was May 12th. On June 10th the red blood count was 1,500,000; the hemoglobin 25 per cent.

During this exacerbation of his anemia, the spleen was two finger breadths below the costal margin and he had fever every afternoon. He is in another remission. He is weak, as you see; complains of dyspepsia; has evidence of changes in his cord, viz., hyperactive upper extremity reflexes, unequal knee jerks, and some impairment of coordination in his upper extremities. His liver is three cms. below the costal margin, spleen is not palpable at this time. Spastic anal sphincter. His blood picture on August 6, 1925, was hemoglobin 40 per cent.; erythrocytes, 1,680,000; color index, 1.2; marked achromia; poikilocytosis and anocytosis; macrocytes but no nucleated reds.

Just this week mercurochrome (2) twenty c. c. of a one per cent. solution has been given intravenously. As to the results of this type of treatment we hope to have something to say at the next clinic.

Case IV.—History No. 6806-BF; admitted to this hospital March 30, 1925, complaining of weakness, gastrointestinal disturbance, stumbling in the dark, and loss of twenty pounds weight in the last three months. Aged sixty-four, he had dysentery in 1898, which was first diagnosed pernicious anemia in Government Hospital No. 59, where he was confined in bed for ten weeks the latter part of 1923. In February, 1925, he had a remission.

His weight was 156 pounds; fair amount of subcutaneous fat; first degree edema of legs and ankles; arcus senilis; sclera, icteric; heart, enlarged to the left; systolic murmur at apex; protruding hemorrhoids; free fluid in the abdomen; spleen, palpable; liver three finger breadths below the costal margin. There was a slight fullness in the epigastric region which was tender to palpation with some muscular rigidity. There was a slight suggestion of a tumor mass under this area. There is one small hemorrhoid but four tests all show no occult blood in the stool. X ray findings on G. I. series show slight six hour retention in the stomach; evidence of adhesions; evidence of colitis. Gastric analysis showed an absence of hydrochloric acid; red blood cells, 2,360,000; hemoglobin, 40 per cent. Nervous system, corneal reflexes were absent; pupils, irregular and reacted unequally to light; he had a marked weakness; inequality of the deep reflexes of the upper extremities; poor coordination of the same; knee jerks and tendon achilles reflexes were absent.

In spite of the blood transfusions, of five hundred

*From Department of Internal Medicine, Soldier's Home Hospital, Sawtelle, California. Clinic held for the Santa Monica Branch of the Los Angeles Medical Society, August 11, 1925.

c. c. each, today his hemoglobin remained 27 per cent., red blood cells 900,000, which gives a color index greater than 1.

On account of cord changes, absence of hydrochloric acid, and his blood picture, the condition had been diagnosed as pernicious anemia secondary most likely to gastric ulceration, possibly malignant, for we are mindful of a history of internal hemorrhage eighteen months prior to his admission. He is one of the oldest patients we have studied. How long he has been suffering and how many recrudescences he has had we do not know. It is a fact that the cause for the grave anemia, as well as that in Case III, has not been discovered.

The most pertinent question in regard to pernicious anemia is its etiology (1). Shuman at the previous presentation of these cases before you concluded that, "first, pernicious anemia as a diagnostic entity should be relegated." "Second, that it has as a cause a long standing toxemia." "Third, this toxemia is usually due to bacteria, causing a high grade hemolysis, which exhausts the blood forming system."

He considered that, "its cardinal symptoms: grave anemia, hemosiderosis, general weakness, moderate loss of weight, tachycardia, fever, increased metabolic rate, gastrointestinal, visceral, and cord changes were the result of a defense reaction of the body, as a the blood destruction in Addisonian anemias is due to a bacteriolysis destroying the invading organism and liberating the toxic molecule which is then free to combine with the body cell (for example, the cord cell) and in the case of the erythrocyte causing a high grade hemolysis formation without a correspondingly high antihemolysis formation."

In a review of some of the recent literature on grave anemias, the general tendency as O. B. Hunter (2) pointed out is to discard the idea of essential anemias and to regard them all as secondary, or as a symptom of a disease complex. He concluded "that the blood destruction in Addisonian anemias is due to some hemolytic agent and not faulty proliferative activity on the part of the bone marrow; the hyperplasia seen therein, being a regenerating effort to keep up with lysis.". In that connection Christian (3) cites "a close clinical similarity between patients with pernicious anemia and those with polycythemia." Calling attention to the fact "that both too little and too much blood can cause similar symptoms the blood and bone changes found in both conditions being perhaps secondary and relatively often unimportant." It has been pointed out "that the blood picture in pernicious progressive anemia is no different from many other chronic hemolytic anemias, with definite etiological bases."

In the Todd classification of anemias the progressive pernicious anemia (Addisonian type) is placed among those due to hemolysins or increased fragility of erythrocytes," as Shuman stated in his paper.

O. B. Hunter (2) observed "that all of the cases in his series, either showed a frank pyorrhea alveolaris or increased amount of oral bacterial flora, spirallary forms.

P. B. McLaughlin (4), "assuming from the pathology found, the usual periodical rise in temperature, and the jaundice which is almost continually present, decided pernicious anemia, in all probability is caused by infection," and used mercurochrome as an antiseptic intravenously in its treatment and obtained surprising results in bringing about a remission in the disease.

Postoperative Parotitis

JOSEPH K. NARAT, M.D.
Chicago

Postoperative parotitis while not a frequent postoperative complication is an interesting phenomenon which deserves more attention and study than has been accorded to it.

Munde (1) described as early as in the seventies the occurrence of postoperative parotitis after ovariotomy. The first reported cases all followed operations on the female reproductive organs. Paget (2), however, in 1886 directed attention to the fact that parotitis may develop as a rare secondary manifestation following various operations in the lower as well as in the upper abdomen.

The infection may be carried to the parotid gland by three different ways: 1, hematogenous, 2, lymphogenous, 3, ascending, i. e., by way of Stenson's duct. The primary focus of infection is usually localized either in the oral cavity, which harbors a multiplicity of germs, or in the abdominal cavity where the bacteria may have been present before, or were inoculated during, the operation.

Contributory factors in the development of postoperative parotitis are as follows: the pressure on the parotid gland during manipulations on the jaw by the anesthetist; the lack of mastication resulting in stagnation of infectious material in the oral cavity; the dryness of the mouth following anesthesia, favored by the administration of purgatives and atropine before operation, and the limited intake of fluids after the surgical intervention.

Pathologically the infected parotid gland may present a picture of a simple inflammation or the infectious process may progress to a diffuse or circumscribed suppuration; a real gangrene is sometimes observed.

The postoperative parotitis usually begins between the third and the seventh day after the operation. The local symptoms consist in stiffness of one or both sides of the face and swelling of one or both parotid glands with pain on pressure. The general symptoms are: malaise, elevation of the temperature and pulse rate, leucocytosis. The prognosis is serious: Wagner states that postoperative parotitis ends in death in thirty per cent. of the cases.

In regard to the therapy nearly all the authors recommend an early institution of surgical treatment. Fantozzi (3), advises incision at once. Fischer (4), Friedrich (5), Wagner (6), Collins (7), express the opinion that a free incision and drainage should be resorted to early. Blair (8) also is in favor of an early surgical procedure. Le Dentu (9) thinks that the revealing of the suppuration ought not to be awaited. Frank (10) concludes from his experience that when the swelling does not show any tendency to decrease in size in about four days, it is advisable not to wait for fluctuation, as the location of the pus is beneath the dense parotid fascia.

Our experience does not support this view as can be seen from the following history.

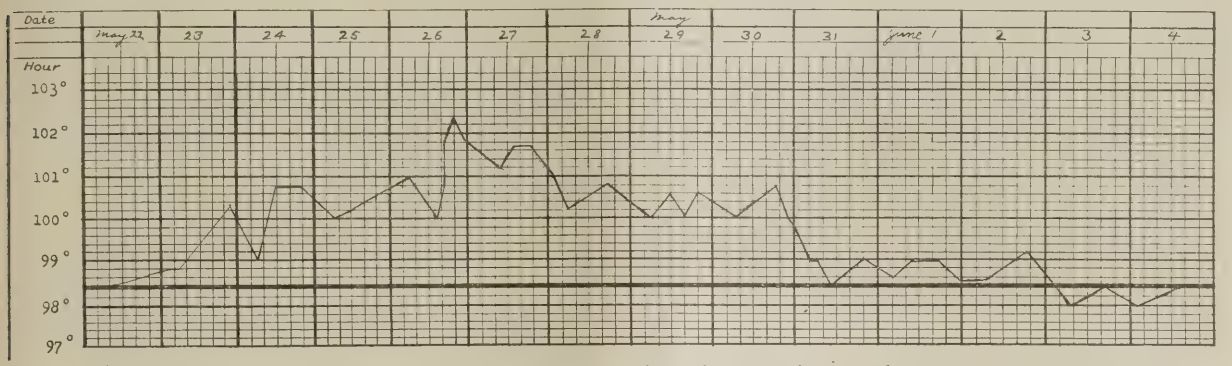

FIG. 1.—Temperature chart of patient whose case is reported.

REPORT OF CASE

CASE.—A woman, aged forty-eight, married, was admitted to the Lutheran Memorial Hospital on May 22, 1925, with complaints of distress in the hypogastrium and metrorrhagia. The physical examination was essentially negative except for the presence of multiple fibroids in the uterus. A supravaginal hysterectomy was performed the following day in the usual manner. A hypodermic injection of morphine sulphate one sixth grain and atropine sulphate one one hundred and fiftieth grain was given one hour before the operation. The pathological diagnosis was intramural fibromyomata of the uterus. On May 25th, the third day after the operation, the patient began to complain of stiffness in the lower jaw and a numb feeling in the right side of the face. A typical mumps was visible the following day. The leucocyte count was 16,900; the erythrocyte count 4,700,000, hemoglobin was eighty per cent.

Applications of hot boric acid and alcohol solutions were ordered and a mouthwash used every hour. The condition of the teeth was good. On May 27th, the fifth postoperative day, a fully developed parotitis on both sides was present. The swelling had a hard consistency, and there was a bluish discoloration of the skin over the affected area. Under continuous hot compresses, interrupted only by daily applications of therapeutic light the swelling of the parotid glands regressed without any surgical intervention and the temperature which reached 102.4° on the fourth day after the operation was normal on the twelfth day. The patient left the hospital on the thirteenth day in perfect health.

We believe that in regard to the prophylaxis the necessity of oral hygiene should be emphasized. The condition of the teeth should receive the attention of the surgeon before the operation. After the surgical procedure efforts to maintain normal secretion of saliva should be made. Lemon stick candy promotes salivation in a satisfactory way. If a postoperative parotitis develops not only the local but also the general condition of the patient should be taken into consideration, when the question of surgical intervention is discussed. Daily leucocyte counts are advisable; a rising count indicates suppuration; because of a dense fascia fluctuation may not be present or appear very late. If there are no signs arousing suspicion of a developing septicemia and if the general condition of the patient is satisfactory a conservative treatment may be instituted, consisting of antiseptic mouthwashes, promotion of salivation, compresses of hot boric acid and alcohol solutions supplemented by applications of therapeutic light. A watchful observation of the patient is essential; aggravation of the symptoms necessitates incision and drainage, but many disfiguring scars may be avoided if the patient is treated according to the rules outlined above.

The Modern Treatment of Fractures of the Lower End of the Radius

RALPH M. CARTER, M.D., F.A.C.S.
Green Bay, Wisconsin

For some time past injuries in the region of the wrist joint, more especially fractures of the lower end of the radius, have occupied a considerable share of my attention and study. Several factors were responsible for my interest in the subject.

In the first place, fracture of the lower end of the radius is without doubt the most frequent fracture coming under the care of the general practitioner. This is readily shown by a study of any large series of fractures in general, and this fact alone is sufficient to give it marked importance, in view of the severe disability which may and does follow improper treatment.

Furthermore, as others have shown, and as recent work of my own demonstrates (1), fractures of the lower end of the radius fall into two great classes, depending upon whether or not union of the radial epiphysis has occurred; within each of these classes, in the vast majority of cases, the pathology of the fracture is peculiar to the class to which it belongs; it is always the same as regards site of fracture, displacement, and other factors, and differs only in degree of severity, depending probably upon the extent and violence of the force producing it. This is true of no other fracture, unless it be with the possible exception of the socalled Pott's fracture. Such being the case, it would seem that a standardized treatment, applicable to practically all of these cases, might be evolved and generally adopted, which with but few exceptions would give uniformly good functional endresults. The modern method of treatment, to be described later, fulfills these requirements, and gives good results; but judging from some of the cases which I have seen in my own work, while the method may be generally known, it is far from being generally practised, at least so far as some of the details are concerned, and it is upon these details that success or failure depends.

In addition to these considerations, with widespread workmen's compensation laws such as exist today, fractures of the radius assume an economic importance, both to the patient and to the employer or insurance carrier, which they have never had heretofore. While not common in industry in general, nevertheless the aggregate loss as a result of these fractures is considerable, and any measures which tend to shorten the temporary, and reduce the permanent disability are of great value, since individuals are thus kept out of the handicapped class, and the financial burden upon society at large is thereby somewhat lightened.

These are all excellent reasons for the careful study of fracture of the lower end of the radius. It is a subject of importance for every physician in active practice. Formerly such fractures were reduced more or less completely, or if impacted, frequently an attempt was made at reduction; they were then immobilized in a circular cast, often with the wrist in an unnatural and distorted position, and Nature allowed to take her course for a period of five or six weeks. In a large majority of cases, the result of this treatment was a hand and wrist more or less permanently disabled and deformed; not infrequently, the degree of disability was great enough to produce a distinct handicap in the use of the hand; far too often it was of such an extreme grade that the hand was practically useless. This was especially true if the patient was middleaged. Today such a result in the average case is a reflection on the physician in charge, and simply means gross negligence. If the condition under discussion is treated according to the modern principles of fracture management, the outcome is nearly always good. Let it be distinctly understood that I have reference here to the average case; in the unusual one, in which are associated extreme comminution of the fragments, marked displacement, and severe and extensive damage to the soft parts, we may with justice expect a certain amount of permanent disability, although even in such a case, the results are often surprisingly good. Under these circumstances, the surgeon can only do his best. But I believe that any one having occasion to examine any considerable number of claimants for compensation, cannot fail to be convinced that there are still too many poor results in the average case of fracture of the lower end of the radius. To emphasize once more the essentials of the modern treatment of this fracture is the purpose of this paper.

It was formerly generally taught and practised that the proper treatment for the socalled typical fracture of the radius was reduction, followed by fixation of the hand in a position of volar flexion and adduction. The dressing, frequently a circular cast of plaster of Paris, was left on for two or three weeks before it was disturbed, after which attempts at passive motion and massage were begun. The results of such treatment were highly unsatisfactory in a great many cases, consequently modifications of this method began to be tried. These at first consisted principally in shortening the time of fixation, and in beginning the functional treatment earlier. The results of this still left much to be desired, and some few surgeons advocated purely functional treatment, using practically no fixation whatever; Lucas-Championnière even disregarded reposition of the fracture. The latter teaching gained but little acceptance, and has now rightly been abandoned; but treatment without fixation still has some advocates. Theoretically, to my mind, it undoubtedly has some advantages; practically, with the average ambulant patient, it cannot be employed. The danger of a new dislocation is always present, pain is often more severe than when fixation is employed, and occasionally late absorption of the primary effusion with excessive callus formation has been observed. Furthermore, even though these objections could not be urged against this method of treatment, I am of the opinion that patients generally would not readily accept it, for the average layman cannot believe that any fracture can be treated without some form of splint. Under such circumstances, if the result of

treatment were not all that could be desired, the attending surgeon would find himself the subject of much unpleasant criticism, and it is conceivable that he might find it necessary to defend himself in court.

To offer any assurance of success, the method of treatment employed must take into consideration the complete pathological picture of the fracture. It cannot be directed exclusively toward bony union, disregarding the soft parts and joints, as is the case with the older methods; nor can the break in the bone be practically ignored, as is done when fixation is not employed. Therefore, modern successful treatment of fractures of the lower end of the radius depends upon three factors: first, early and complete reduction; second, proper and intelligent application of immobilizing apparatus, with the hand and wrist in a physiological position, and third, the early and intelligent employment of massage and passive motion. These factors are all interdependent, and are all equally important; neglect of any one of them will jeopardize the ultimate success of the treatment. If we consider each of them a little more at length, it will be obvious why this is true.

With the exception of simple fracture of the styloid of the radius, in which there is usually no displacement, reduction, or better, reposition of the fragments is indicated as the first step in the treatment of practically every case of fracture about the lower end of the radius, including those with impaction. The necessity for complete correction may be better appreciated if we analyze the displacement present in the average case. It is not a simple backward displacement of the lower fragment. In the first place, this lower fragment is carried backwards and a little upwards, as a result of the direct violence at the moment of fracture; secondly, as a rule, in falls particularly, due to the fact that the main violence is received by the thenar eminence in the extreme pronated position of the hand, and also due to the fact that the ulnar side of the radius is more or less firmly attached to the ulna by the inferior radio-ulnar ligament, while the radial or outer border is free, this outer side of the lower fragment is displaced more than the inner; the wrist and hand follow the small fragment, leading to a greater or lesser degree of abduction; and lastly, in addition to displacement of the lower fragment *en masse,* it also undergoes some rotation about a transverse axis, with the result that the articular surface is directed posteriorly as well as downward. Since any one of these displacements will give rise to interference with the function of the wrist joint, by changing the plane of the radiocarpal articulation, the importance of complete reduction becomes readily manifest.

Now, how is this reduction to be accomplished? As a rule, it is a comparatively simple procedure. While it is undoubtedly true that many fractures can be reduced while the patient is fully conscious, nevertheless I believe that in most cases better work can be done under general anesthesia. The latter is a necessity in hypersensitive patients, and in neglected or difficult fractures. A cardinal principle in the reduction of all fractures is muscular relaxation and this must be as complete as it is possible to obtain. It is very necessary in fractures of the lower end of the radius, and frequently can be secured only by having the patient anesthetized. The technic of reduction which I use, and which I believe to be capable of the most general application, is as follows: The hand of the patient is grasped by one hand of the operator, whose other hand surrounds the patient's forearm with the thumb over the site of the fracture, in a position to exercise pressure on the lower fragment. The wrist is then placed in a position of extreme hyperextension, which relaxes the muscles and the dorsal periosteum over the fracture, if it is not torn through. The latter condition is not infrequently present, and under these circumstances this untorn bridge of periosteum, tightly stretched as it is by the dorsal dislocation of the lower fragment, constitutes a decided obstacle to reduction; it can only be relaxed by extreme hyperextension. With the wrist hyperextended, strong traction is made in the direction of the long axis of the forearm, and the fragments are disengaged; when this has taken place, the wrist is brought to a position halfway between flexion and extension, always continuing the traction, but now directing it in a volar and ulnar direction. During this entire maneuvre, strong pressure by the thumb of the other hand forces the lower fragment into place, and reduction is complete. When the traction is relaxed, the fragments again lock in their new position, and in most cases there is very little tendency for the dislocation to recur.

Let it be understood that I am here discussing the reduction of the usual fracture, the one in which the lower fragment is not splintered, and in which the simple dorsal displacement is present; these cases constitute the large majority of all encountered. When we have marked comminution of the lower fragment with extensive involvement of the articular surface, great adduction of the hand, possibly fracture of the shaft of the ulna, or other serious complications, it then becomes a question of doing the best we can under the circumstances; the fragments must be manipulated into their proper positions as near as possible, after which attempts are made to mold them into shape. Even in such cases, with careful and painstaking aftertreatment, the results are often surprisingly good.

Complete reduction having been accomplished, proper immobilization to prevent a recurrence of the displacement while healing of the fracture is in progress next engages the attention. The method of immobilization is just as important as reduction; indeed, without underestimating the value of a careful approximation of the fragments, it should nevertheless be decidedly emphasized that the method, and particularly the position of fixation, is of greater importance as regards the extent of the disturbances existing after removal of the bandages. The old view that the hand, after replacement of the fragments, should be placed in a position of volar flexion and pronounced adduction, by which I mean ulnar deviation, is open to criticism from several angles. Any extreme position of a joint, if maintained for any length of time, is unphysiological, and this applies particularly to the wrist joint under the usual conditions of fracture of the lower end of the radius. With the wrist in strong volar flexion, the extensors of the fingers are strongly stretched, while the flexors are correspondingly relaxed; the overstretched extensors, as a result of pain produced in them, may spasmodically contract still more, giving rise to a

force tending again to displace the distal fragment dorsally and proximally. Disregarding the discomfort of the position, however, and assuming that any displacement is prevented by the retentive apparatus, a greater danger to the future functional usefulness of the hand and wrist still exists. This is the extreme likelihood of adhesions on the flexor aspect of the forearm and wrist. That this danger is a real one is obvious when we consider the injuries to structures other than the bone which are present at the time of fracture. Hemorrhage and exudate into tendon sheaths and joint, frequently more or less tearing and laceration of the joint capsule, injuries to articular cartilage, some or all of these associated conditions are always present to a greater or lesser degree; with the hand in a position of volar flexion, late or incomplete absorption of exudate, organization with scar formation, leading to contracture of tendon, muscle, or joint capsule, these cannot do otherwise than lead to marked disability. Massage and passive motion for a brief period each day cannot overcome the evil consequences of fixation in extreme volar flexion; some range of motion may be recovered, it is true, but full and effective extension, the only position in which a strong grip with the fingers can be exerted, will always be lacking, to some extent, in the great majority of cases.

The position of adduction likewise serves no particular purpose. It was formerly thought that there was a certain amount of lever action associated with this position, which might lead to some lengthening on the radial side. That this theory is practically without foundation may be readily seen when one reflects for a moment that the fulcrum of this lever could only be the styloid process of the ulna, and that this is very frequently broken off. Nothing is to be gained by dressing in adduction; on the contrary, frequently a typical deformity is produced.

All these objections and difficulties are met and overcome by the simple expedient of immobilizing the wrist in the natural position; that is, with the elbow flexed at a right angle, the forearm in a mid-position between pronation and supination, with the axis of the hand forming a prolongation of the axis of the arm, or with slight dorsal flexion at the wrist joint. Contrary to the old view, in such a position there is no tendency to displacement of the fragments. No pressure is brought to bear on the articular cartilage, consequently the joint has no tendency to stiffen. All the opposing muscles and tendons of the region are in a state of equilibrium, consequently of physiological rest, thus doing away with the danger of future contracture. In this position only, with proper retentive apparatus, are the fingers capable of exercising at all times strong, active movements of flexion and extension, without which are bound to occur muscle atrophies and trophic disturbances, with stiffening of the interphalangeal joints. Last but not least, from the patient's viewpoint, a wrist thus immobilized is perfectly comfortable. These are not mere statements, but are facts of which anyone can convince himself. The old cramped uncomfortable position of volar flexion and adduction has no place in the modern treatment of fractures of the lower end of the radius, unless in the very exceptional cases with a marked tendency to displacement of the fragments which cannot be overcome in any other way. Even in such cases, after callus formation has begun, the natural position as described above can be adopted, with nothing but benefit to the ultimate result.

The method of dressing is also of importance. From what has been said, and in accordance with the modern view of the treatment of fractures about the wrist joint, it is very obvious that the old circular plaster of Paris cast has no place here. If one so desires, a molded plaster splint may be employed, especially if the position of fixation in slight dorsal flexion is chosen. There are also various manufactured splints obtainable which have their advantages and disadvantages. In my experience, light anterior and posterior wood splints fulfill every requirement for the average case. When properly applied, perfect fixation is obtained, they are easily removed for inspection, massage, and passive motion, and they are comfortable. The anterior splint extends from just below the elbow to a point just proximal to the distal heads of the metacarpals, the posterior one occupying a corresponding position on the back of the forearm and hand. Both should be cut out to allow for the thenar eminence and the head of the ulna, respectively. They should be well padded, and in addition, a small pad should be placed beneath the posterior splint at the site of fracture to prevent any recurrence of the displacement, and anteriorly, the space between the head of the radius and the splint should be filled in with one or two extra pads. The splints are applied with the hand and arm in a position halfway between pronation and supination; they are held in place by adhesive plaster strips, and a bandage put over all. Dressed in this way the arm should be perfectly comfortable; any marked pain, any throbbing, any blueness, coldness, or numbness of the fingers, is an indication that the dressing is too tight, and the condition should immediately be remedied.

From the very first day following application of the splints, patients are urged to practise frequent movements of the fingers, especially closing of the fist, and movements of the elbow. They readily do this, because pain is conspicuous by its absence. The shorter the period of immobilization, the shorter the healing period, and the better the result. As a result of this early and frequently repeated movement, stiffening of the fingers and atrophy of their muscles do not occur; likewise an excellent effect is produced in the region of the wrist joint by the action of the long finger muscles, flexors and extensors; the same is true of the short muscles of the palm.

In addition to these active movements, the importance of which should be impressed upon the patient, treatment by massage and passive motion is carried out. In most cases I have found that this can be begun by the third or fourth day, obviously employing the utmost gentleness. In the case of a fracture showing a marked tendency to displacement, the time for beginning these manipulations may have to be deferred somewhat; but the earlier they can be started without jeopardizing bony union, the better the ultimate result. This treatment is directed mainly toward preserving the function of the wrist joint; for the purpose of administering it, the dressing is completely removed, and in the beginning, very light massage and extremely slight passive motions are

instituted. At first the time should be short, and throughout absolutely no pain should be caused. This management is repeated daily if possible; if not, every other day, at each sitting lengthening the time of massage, and slightly increasing the amplitude of the passive motion, always being careful to avoid giving rise to pain.

In deciding the proper time to begin to discard permanently the retentive apparatus, the age of the patient, the extent of the displacement, and the solidity after reposition are factors which must be taken into consideration, and no hard and fast rule can be laid down. Generally, by the tenth day, the anterior splint may be discarded altogether, and by the fourteenth, the patient may begin gentle active movements, in addition to the passive ones. A few days later, or by the end of the third week, the posterior splint may be taken off, a firm supporting dressing of gauze and adhesive tape being applied about the wrist at the site of fracture. The sling, however, should be retained, and passive and active motions and massage continued. By the end of the fourth week union should be firm enough for the patient to begin to use the wrist for light tasks; however, this early activity should involve absolutely no strain on the newly formed bone at the site of the fracture. The average case should be able to return to light manual labor at the end of six weeks, but full, heavy work, involving marked strain and stress on the wrist, should not be attempted before the tenth or twelfth week.

If the treatment just outlined is conscientiously carried out, excellent results will be obtained. In the average case recovery will be complete, both from an anatomical and functional point of view, and in those occasional cases showing more severe injuries to the associated structures of the wrist joint, the result will be surprisingly good. And good results amply repay one for the time and attention to detail which is necessary to secure them.

Cholecystitis During Pregnancy

HARRY KOSTER, M.D., F.A.C.S.
Brooklyn

An investigation of the literature indicates that cholecystitis, as a recognized complication of pregnancy, is not an oft recorded condition. The discussion of this subject found in textbooks is meager, Williams merely mentioning it in a paragraph of about eighteen words. Going back as far as 1899 I find that less than forty cases, proved by operation or through finding calculi in the stool, are recorded. And yet, careful inquiry into the history of female patients suffering from cholecystitis and cholelithiasis, elicits the information that from 73.4 to ninety per cent. of them have borne children and that ninety per cent. of these can refer the beginning of their gallbladder symptoms to some particular pregnancy. Grube's figures are 73.4 per cent.; Peterson in his series finds seventy-five per cent.; MacLaren and Ritchie make it about eighty-five per cent.; while Schroeder's figures are ninety per cent. If then, in the life of woman, the time for development of cholecystitis and cholelithiasis is during the child bearing period, the question of the causal relationship of the pregnancy to the disease becomes an interesting one.

Nonneoplastic surgical diseases of the gallbladder and bile ducts excepting catarrhal inflammation resulting from chemical intoxication, such as acute phosphorus poisoning, have as their causative agent an infection by bacteria. In general, infections of the gallbladder may occur by three routes:

1. Direct continuation of the infection through the duodenal papilla or its lymphatics. The possibility of such direct extension is borne out by the presence of round worms in acutely inflamed gallbladders not containing stones. The old idea, still expressed in some textbooks of physiology, that human bile possesses antiseptic properties, is no longer tenable; indeed, bile may be used as a culture medium for certain organisms. Of course, organisms are rare in the duodenum and it is difficult to understand how they might ascend against a normal bile stream. The sphincteric action of the ampulla of Vater which exerts a pressure equivalent to 600 m.m. of water, and the flushing of the duct and ampulla by the intermittent passage of bile into the duodenum, both tend to prevent organisms from gaining entrance to the biliary tract from the duodenum. Bond, however, has shown experimentally that it is possible for bodies to enter the common duct from the duodenum and travel upward against the stream. Obstruction in the duct favors the growth of bacteria, by furnishing a favorable medium in stagnant bile. Charcot, Gombault, Naunyn and Sherrington independently found that the bile became infected shortly after ligature of the common duct.

2. Another source of infection is by way of the portal circulation. Adami demonstrated bacteria in the deeper layers of the intestine, in the portal circulation and in the liver, under normal conditions. He believed that the leucocytes carried bacteria to the lymphatic and portal vein radicles. The natural bactericidal powers of the liver cells are sufficient to destroy most of the organisms, but diminished destructive activity of the liver cells resulting from disease, fatigue and malnutrition makes it possible for some bacteria, escaping destruction, to be excreted with the bile. Lartigan tied the common duct in animals and then fed them bacteria. He recovered the organisms from the gallbladder in over fifty per cent of the animals, thus demonstrating the possibility of infection descending from the liver. Organisms of attenuated virulence entering the portal system and eliminated with the bile, may make their habitat in the gallbladder.

3. Certain organisms show a selective affinity for particular tissues. They reach them after dissemination through the blood stream from some focus. Streptococci and colon bacilli removed from acutely inflamed gallbladders and injected intravenously into animals produce cholecystitis. The influenza bacilli and the diplococci of pneumonia have been isolated from acutely inflamed gallbladders in patients suffering from influenza and pneumonia, respectively. Typhoid bacilli injected into the ear veins of a rabbit whose cystic duct had previously been ligated were recovered from the gallbladder.

Bearing these routes in mind, there are certain conditions present during pregnancy which favor the appearance and growth of bacteria in the gallbladder, thus becoming causal factors in the close relationship between pregnancy and cholecystitis. The increased size of the uterus during pregnancy produces increased intraabdominal pressure. The intestines are displaced upward and stasis of bile occurs as a result of mechanical derangement. This, of course, favors infection. Overeating, following the initial anorexia incident to the usual early month vomiting, is a common occurrence among parturient women, if for no other reason, because of the desire to insure a plentiful reserve for the growing fetus. This places an increased burden on the liver, and organisms can more readily escape into the bile.

As pregnancy progresses, metabolic activity is increased. The mother has the added burden of eliminating fetal products. Goldsborough and Ainley showed that through the entire period of gestation the normal obstetrical patient eliminated more slowly than the normal nonpregnant person, and that in the last months of pregnancy the power to eliminate fell far below that of the nonpregnant. The liver, taxed by the increased amount of waste products, becomes less potent as a bacterial filter and gallbladder infection is thus facilitated.

After the early months hemorrhoids are commonly noted. They are a direct result of stasis caused by the pressure of the uterus and offer an easy pathway for colon bacilli to enter the portal circulation. A somewhat similar, although not so marked, condition of stasis is found in the other tributaries of the portal vein, but the hemorrhoidal veins are the most prominent offenders.

There is an increase in the cholesterin of the bile during pregnancy. This is not due to stagnation of the bile, but to hyperactivity of the cells lining the gallbladder. Kramer grew colon bacilli in a sterilized mixture of alkaline peptone, bouillon and bile, and obtained a gradual precipitation of cholesterin and other components of gallstones. At the end of four weeks a closely packed semisolid mass resulted, and after six months' growth, the supernatant fluid was poured off leaving a well moulded mass resembling soft gallstones. He suggestd that the precipitation was due to the acid reaction of the bile resulting from the growth of the colon organism. The increased cholesterin content during pregnancy, once infection is introduced, favors the pathogenesis of gallstones.

Constipation is a frequent concomitant of pregnancy. Physical inactivity, because of selfconsciousness, actual cumbersomeness, and desire to protect the fetus, is the rule rather than the exception during parturition. This, with venous stasis in the intestines, pressure of the growing uterus and fetus, and the inefficient contractions of the attenuated accessory muscles of the abdominal wall, are responsible for the frequency of constipation during gestation. And constipation in turn explains the increased eliminative difficulties of the liver, and the increased possibilities for migration of organisms into the portal system.

These conditions developing during, and as a result of, pregnancy, all favor infection of the gallbladder. They are the connecting link between the etiological factors of cholecystitis and the pregnancy, and explain the relationship between a definite pregnancy and the history of the occurrence of the first attack in such a large percentage of cases.

That many cases of cholecystitis during pregnancy have not been reported is probably due to the fact that of those encountered comparatively few come to operation. Many attacks of pain in the upper abdomen with nausea, some temperature, and anorexia, that have been explained as indigestion because of mechanical conditions, have been gallbladder infections not recognized as such.

Routine inspection of the gallbladder during laparotomy for lesions elsewhere in Peterson's series of 542 cases revealed gallstones in 11.8 per cent. and a subsequent review of the case histories showed that while the preoperative diagnosis of cholelithiasis would have been warranted in a large percentage of cases, comparatively few had a story of sharp, acute attacks. We must recognize that mild inflammations of the gallbladder are possible, that these inflammations may result in the formation of stones, and that only at some later time, perhaps after years have elapsed, may an acute attack ensue, which would bring the case to operation where the diagnosis would be verified. This explains why so few cases come to operation during that term.

Analysis of the few cases that have come to operation shows that in nearly one third of them the onset of symptoms has been during the fifth month. At this time the uterus is approaching the level of the umbilicus, and crowding the intestines upward against the liver. The woman, conscious of her appearance, attempts to conceal the abdominal enlargement by the injudicious use of corsets and further crowds the intestines upwards.

Jaundice was a prominent symptom in approximately sixty per cent. of the cases and in fifty per cent. of these no calculi were found in the common ducts. Since so large a percentage of cholecystitis cases during pregnancy show jaundice without common duct obstruction, and Kehr states that jaundice was absent in one third of his common duct stone cases, it would follow that in cholecystitis during pregnancy jaundice may and does occur in a constitutional way and not only as a result of obstruction. This is a particularly interesting symptom, since jaundice has a tendency to initiate uterine contractions and is a menace to the fetus. The nearer to term the greater the possibility of exciting labor.

Pain in the upper right quadrant of the abdomen, radiating to the back and shoulder, is significant. Frequent urine examinations are necessary to rule out pyelitis which more often attacks the right kidney pelvis because of the dextroobliquity of the uterus. The demonstration of traces of bile decides

the diagnosis in obscure cases. Chills and fever suggest obstruction to the common duct, and when the common duct is obstructed jaundice is the invariable concomitant.

The surgical aspect of cholecystitis during pregnancy does not offer any special problems. Operations when the complications are not serious have but little tendency toward producing an abortion. It must be remembered that cholecystitis tends to subside and that long periods of freedom from symptoms are common, therefore operation should be advised only when the symptoms become frank, and especially if the attacks are frequent and recurring. The nearer to term, the greater the danger of premature labor from operative intervention, therefore, after the sixth month, whenever possible, operation should be postponed until viability.

Operative mortality does not materially differ from that in the nonpregnant state and is dependent upon the degree and extent of the inflammatory process and upon the complication of common duct involvement. The greater frequency of jaundice in the pregnant cases tends to increase the mortality rate. In Peterson's collected cases numbering twenty-three, the mortality rate was 13.04 per cent. (three deaths). It must be remembered that in these cases operation was performed because of urgent indications, therefore the results were very good. Graham reports five cases in which the patients were operated upon during pregnancy with one death. This patient was operated upon in the sixth month and a ruptured gallbladder found. All of these cases showed jaundice. Burke reports three cases with no deaths. Two of these patients were two months' pregnant and one four months, all jaundiced.

The operation of choice is not at all influenced by the pregnancy. The surgeon should be guided by the nature and extent of the inflammatory process and the complications present.

The following case report is presented because of its interest from the obstetrical, gynecological and surgical viewpoints:

Case.—Anna S., aged thirty-three, was admitted to the Brownsville and East New York Hospital October 1, 1922, complaining of pain in the right hypochondrium, vomiting and fever. Her family history was negative as regards this illness. Previous personal history—appetite was good, she was constipated, and vomited occasionally during attacks of pain. Menses began at fourteen, regular, twenty-three day type, four day habit, moderate amount, no pain, last period June 4, 1922. Obstetrical history—married nine years, had had four abortions spontaneously, all during the third month, the last one in December, 1921. With the present pregnancy, as soon as the first period of amenorrhea was noted, the patient consulted a physician who upon examination recognized a pregnancy in a movable retroverted uterus. He reposited the uterus, introduced a pessary to maintain the anteversion, and because of the previous miscarriages and the intense desire of the patient to go to term, kept her in bed up to the day of admission to the hospital.

Present history: Patient had been getting attacks of pain at intervals for the past year, the onset coming immediately after the last abortion. Pain was severe, and usually came after a heavy meal, radiating to the back and across the epigastrium. It was usually accompanied by vomiting. There was no blood in the vomitus, no jaundice, no clay colored stools. The patient complained of pain and tenderness in the right hypochondrium. On the morning of admission the patient had a severe attack of pain radiating to the back and right shoulder, accompanied by vomiting. Temperature 100, pulse 112, respiration 22. Physical examination revealed the following significant facts: Sclera slightly icteric; abdomen obese with palpable uterine tumor of a pregnancy of nearly five months' duration; tenderness and ragidity in the upper right quadrant with a focal point over the gallbladder region. Blood examination showed 18,400 white cells, 86 polymorphonuclears, 11 small and 3 large lymphocytes.

The diagnosis of cholecystitis with cholelithiasis was made and the following day the patient was operated upon. A distended, tense, thickwalled gallbladder almost buried in adhesions by the duodenum and omentum and containing soft stones was found. There were no stones in the ducts. Cholecystectomy and appendectomy were performed and the abdomen closed without drainage. The recovery was uneventful and the patient was discharged after sixteen days in the hospital. She did not return to bed. Subseqeuntly she was free from the preoperative symptoms. Two weeks before the date of her expected delivery she entered the hospital where signs of a toxemia developed with a blood pressure of 185 over 110, edema of the face and hands, visual disturbances, headache, albumin and casts in the urine. She was treated by the McPherson method, the toxemia was reduced and she was finally delivered by forceps of a living child.

One cannot help being struck by the findings in this case. A history of constipation, colic definitely related in time of onset to a specific pregnancy; relation of attacks to heavy meals; occurrence of last attack at the fifth month; presence of jaundice and the late toxemia. Speculation regarding the possible focus of infection in this particular instance would be idle, but so many of the conditions previously enumerated as being causally responsible for the relation of cholecystitis to pregnancy are found in this case that further summing up seems unnecessary.

The Clinical Significance of Visualization of the Gallbladder with Tetraiodophenolphthalein of Sodium*

I. O. PALEFSKI, M.D.
New York

On perusal of the rapidly increasing literature on the examination of the gallbladder by the new opaque method, one is impressed with the importance attached to this procedure. It is asserted that by this method ninety per cent. of cholecystic lesions, even in their incipiency, are easily detected; that nonopaque stones are recognizable by the negative shadows they produce in the opaque gallbladder area and that obstructive conditions in the biliary ducts are determined by the absence of opaque gallbladder shadows. According to some of these observers, even the degree of the excretory function of the liver may be surmised from the time required for the visualization of the gallbladder, since this dye is excreted chiefly through the liver.

In the face of such ostentatious assertions one would be inclined to think that, even if only part of these statements are found valuable, this method has fulfilled its expectations. Our experience thus far enables us to draw the following conclusions:

The gallbladder is not usually visualized in jaundice whether caused by stone, adhesions, cancer at the hilus of the liver, gallbladder or pancreas. In these obstructive conditions, therefore, the results of this method are of secondary importance, as the etiology still remains unascertained. Secondly, the early cases of cholecystitis and cholelithiasis associated with small nonopaque stones are not readily recognized, as no changes are noted in the characteristics of the normal gallbladder shadow and in its sequence. The alleged contrary claims in cholelithiasis are undoubtedly due to failure of the investigators to make a careful preliminary examination, by the ordinary röntgen method for the detection of opaque stones. Thirdly, the chief value of this method lies in the invariably absent gallbladder shadow in obstruction either at the sacculated base of the gallbladder, known as Hartman's pouch or in the cystic duct, by either stone, adhesions, cicatrix or primary growth. We also wish to stress the importance of a faintly outlined gallbladder shadow in many instances of well advanced cholecystitis or cholelithiasis, even if the cystic duct and gallbladder remain partly patent. Graham and his associates attribute this phenomenon to the lack of power of concentration of this dye by the diseased mucosa of the gallbladder. We believe, furthermore, bearing in mind that at least sixty to seventy per cent. of all cholecystic lesions are associated with pericholecystic adhesions, and from analogy of their inhibitory effects upon the pylorus, that these also exert similar effects upon the cystic duct through the circular fibres of its fibromuscular coat. Another possible factor influencing the patency of the lumen of the cystic duct is the peculiar arrangement of its mucosa consisting of loose, spirally situated papilla known as Heister's valves which, under normal conditions, probably have a regulating effect upon the flow of bile into and out of the gallbladder. In inflammatory processes of the gallbladder and biliary ducts, these often become edematous and thus further diminish the naturally narrow lumen of the cystic duct in an analogous manner, as the mucosa at the ampulla of Vater in catarrhal jaundice or cholangitis. The failure in nonjaundice cases, therefore, of obtaining a gallbladder shadow, after the intravenous or intraduodenal methods, but not after the oral (1) is pathognomonic evidence of pathology, obstructive in character, incident to the cystic duct or gallbladder or both. A faintly outlined gallbladder shadow is suggestive, but not conclusive of the existence of nonobstructive pathological conditions.

METHOD OF ADMINISTRATION

Of the three procedures at our disposal the oral method as we suggested (1) and also by Menees and Robinson (2) is the simplest but the least accurate. It appears that the dissolution of the keratin coated capsules containing the dye is determined by the reaction and amount of fluids in the intestinal tract. It was recently pointed out by Sossman, Whitaker and Edson (3) that out of 210 cases, seventy-nine showed none or an extremely faint shadow after this method. Nevertheless, owing to its extreme simplicity, it is advisable to begin with the oral method

*Read before the Harlem Medical Association, New York, October 7, 1925.

Fig. 2.—Pericholecystic adhesions causing cystic duct obstruction. Mrs. B. M. Referred by Dr. B. Stivelman. Cholecystectomy by Dr. William H. Luckett. The gallbladder was not visualized after oral and introduodenal administration. The stones were visualized by a preliminary examination.

first, and if the gallbladder is not visualized, the results must be checked up by either the intravenous or intraduodenal methods. We give with the aid of two glasses of water, twelve five gr. kerosal capsules about 6 or 7 p. m., six hours after the previous meal. This is followed two hours later by the evening meal. Food is then withheld until after the films of the gallbladder are taken at 9 a. m. and 1 p. m. the following day. A bread, cereal and potato lunch is then allowed and films are taken at 5 p. m. and, if necessary, on the following morning.

Since the advent of tetraiodophenolphthalein of sodium the intravenous method became more applicable for clinical purposes, the former being less toxic and is used in smaller doses than the brom salt previously used for this test. With the patient in the prone position and the extremity steadied by an assistant, we introduce, through one puncture, fifty c. c. of a sterile solution of double distilled water into which three gm. of tetraiodo salt was dissolved and filtered through double paper. We use, for the introduction, a fifty c. c. Janet-Frank fingerholed syringe provided with an eccentric tip as it permits manipulation with one hand while with the other the operator steadies the needle *in situ*. The free flow of blood through the needle is necessary before attaching the syringe and iodine and alcohol for asepsis are used. These precautions observed, no bad effects follow. The reaction, if any, is even less disturbing than after the oral method, slight dizziness being the most frequent complaint. Films of the gallbladder region are taken, six, twelve and twenty-four hours later.

In those in whom the gallbladder shadow was not obtained after the oral method or when the veins were not distinctly visible, the intraduodenal method may then be used to advantage. It is as reliable as the intravenous method and the gallbladder shadow follows the same sequence. The tube is introduced in the usual way, on the fasting stomach about 9 a. m. and when it is ascertained that it passed into the duodenum, five hundred c. c. of warm distilled water in which three gm. of the tetraiodo salt is dissolved, is then quickly introduced into the duodenum with an irrigating syringe of one hundred c. c. capacity, and the tube is immediately removed. If vomiting ensues, it is usually gastric contents admixed with bile. It may be advisable to precede

several hours before with a one half grain of codeine sulphate by mouth to prevent possible diarrhea or abdominal discomfort.

CONCLUSION

The tetraiodophenolphthalein test has merited a permanent place among our diagnostic procedures as through it the existence of obstruction in the cystic duct or at the base of the gallbladder is now recognized clinically.

Contrary to expectations, it does not always visualize nonopaque stones, neither are early cases of cholecystitis commonly recognized by this test.

Many normal gallbladders are not visualized after oral administration. The results, then, must be checked up by one of the other methods.

The intravenous method, through one puncture as described above, is not followed by general or local ill effects and gives most dependable results.

The experimental part of this work was developed at the Harlem Hospital. We wish to express our appreciation to Dr. P. Kleinskopf for his assistance and to the staff of the x ray department for their cooperation.

New Clinical Aspects of the Steinach Operation

HARRY BENJAMIN, M.D.
New York

(*Concluded from page* 518)

Frequently those middleaged patients came to me applying for the operation with various subjective complaints suggestive of premature senility. However, no objective symptoms of this condition could be found and no distinct decline in sex ability was stated. In such cases no sufficient indication existed and for the time being the operation was declined and the patient advised to take a vacation or some other form of treatment. Besides Case 69, which is an example for an insufficient indication at the time of the first examination, I would like to describe another case.

Construction engineer, aged forty-eight. Principal symptoms and complaints were: Patient was getting tired very easily, could not concentrate as well as he did and his memory was declining. Sexually he had never been extremely active, never had any venereal disease, had sufficient erections though not quite as good as in former years. Patient was a heavy smoker, had recently worked unusually hard. Examination was negative, blood pressure normal. Testicles rather small but of a firm consistency, prostate normal. No definite disturbances of thyroid or pituitary functions could be diagnosed.

The patient was not advised to undergo the operation for the time being, since the diagnosis of hypogonadism and premature senility was too doubtful. The patient was advised to discontinue smoking and take a prolonged vacation, since exhaustion from actual overwork, with possible chronic nicotine poisoning seemed to be the most probable diagnosis.

As contraindications, I have mentioned in former publications a seriously impaired cardiovascular apparatus and advanced senility with greatly atrophied testicles lacking spermatozoa. To this I might add in a more general way that I do not deem it advisable to operate on a man who suffers from any organic disease of such an advanced state that we would not want to subject his brokendown organism to an increased endocrine activity.

Since this definite general contraindication can be rather easily followed, it seems to me that it is more important to recognize an insufficient indication than an actual contraindication.

Summarizing on indication, I would like to repeat the following:

We have a sufficient indication for the Steinach operation if we believe that a condition is entirely or partly due to a congenital or acquired hypogonadism and if we can expect to produce a back pressure into the testicle by vasoligation.[1] If we are not certain of these two stipulations, the indication is insufficient and we would have to advise against the operation or let the patient know that the chance for a success is nil or correspondingly small.

An example of a case bordering on contraindication is the following:

The patient was a retired banker, aged seventy. Nine years ago he had a slight attack of cerebral hemorrhage, after which high blood pressure was discovered. He was frequently short of breath, easily fatigued, his memory had declined. He had lost weight and complained of a frequent feeling of fullness in his ears. He had an enlarged heart with a systolic blood pressure 220. He had a fairly normal right testicle. The condition of the left was doubtful on account of a pronounced varicocele on that side. His prostate was somewhat enlarged.

Considering the former apoplexy and the present physical condition of the patient, who generally appeared rather robust and fairly well nourished for his age, I have not expressed any great confidence in an

[1]In cases of sterility, it is somewhat doubtful but by no means impossible that such back pressure can be produced by vasoligation. If sterility is due to complete atrophy of testicles, the chance of vasoligation is almost nil, anyway considerably smaller than if sterility is due to an old infection that has caused an occlusion of the vas. Such an occlusion may not be complete and small amounts of secretion, although no spermatozoa, may pass, allowing back-pressure on ligation. Furthermore, we may ligate below the place of occlusion which means nearer to the testicle, and we may thus succeed in producing a renewed increase of pressure with possible favorable results. This would also explain the success of a repetition of vasoligation. (Vide Case 41).

immediate success of the operation and the patient has not insisted to have it done. He, like so many others, had probably read unwarrantably optimistic and exaggerated accounts and felt disappointed when he received conservative information. I have not absolutely advised against the operation in his case and would have consented only after some precautionary measures: First, I would have tried to reduce the extremely high blood pressure by conservative means, mainly rest in bed for several days, then operated on one side, keeping the patient in bed for about one week or longer following the operation, forbidden all mental and physical strain for several months and, possibly, if no sufficient benefit was derived from the unilateral ligation, would then have performed the operation on the other side. With such management, I do not believe that the operation could have done any harm.

With the exception of cases with a clear contraindication, or closely approaching one, I am convinced that the operation is never injurious. I can by no means agree, for instance, with Payr, Steindl, Schinz and Slotopolski, who lay so much stress on individual contraindications. It seems to me much more logical and much more in accordance with facts to give indications and contraindications in a general way according to common sense and our present conception of the histological and functional changes following vasoligation. For instance, to name mental diseases as contraindication, as Payr does, may at times be correct, namely, if the mental disease is due to or associated with hypergonadism. If the opposite, hypogonadism, exists, a good chance to benefit the patient may be lost by excluding the operation. (vide Case 94.) In not a single case that I have observed have I received the impression that the operation has ever done any harm and, indeed, the majority of clinicians who have studied the subject are in agreement as to the harmlessness of the procedure.

Laughlin and Clark have reported on vasoligation resorted to for eugenic reasons and have, in thousands of cases, never observed any injurious effects.

However, as I have done in a former publication, I would like to emphasize the fact that definite harm could come from the success of the operation, not from the operation itself. The old man, who has regained some of his former vitality, not only sexually, but in other capacities as well, is easily tempted to abuse his newly gained abilities and should most earnestly be warned not to change his mode of living for quite some time. He should enjoy his benefit moderately in work as well as in pleasure and if he will heed this warning no harm can befall him.

After having discussed indications, contraindications and possible dangers, let us briefly consider the results of the cases from various angles. Premature and physiological senility, although separately named in the single case histories, shall be considered together as far as the results are concerned.

Altogether seventy-five patients showing pronounced or beginning premature or physical senility have been operated on.

Of these seventy-five cases, fifty-seven could be followed up and have been observed sufficiently long (that means at least six months) to justify a conclusion. Of these fifty-seven cases, only four cases were decidedly negative, which means seven per cent. Nine cases were considered subjectively positive, nine cases doubtful and thirty-five cases have been more or less strongly but clearly positive. Considering the thirty-five positive and nine subjective positive cases together, as those that have derived a benefit from the operation, we would have to say that seventy-seven per cent. have had a beneficial result. Not all of these forty-four positive cases have noticed a sexual stimulation but only twenty-three, which means about fifty per cent. Twelve out of the forty-four positive cases were generally but not sexually benefited. In two of the negative and doubtful cases, however, the patients were improved as far as their sexual impotence was concerned.

Altogether twenty patients were operated upon bilaterally and fifty-five unilaterally. In forty-one of the unilateral cases a result could be determined and thirty-one of them were successful, which means seventy-six per cent. Of the bilateral cases fifteen could be followed up and thirteen of them were positive, which means eighty-seven per cent.

This speaks for the greater efficiency of the bilateral ligation, which at the same time usually produces prompter and stronger results also. Steinach has made similar observations and I am inclined to advise bilateral ligation in those cases where sterilization will be of no concern to the patient. This is true for most cases of actual senility. Unilateral ligations will be the method of choice where a slow socalled tonic action is desired or where—as in premature senility of the middleaged man—the procreative ability should be retained.

Outside of the cases where senility or hypogonadism was the indication, fifteen patients were operated upon for various other reasons, sometimes with the idea that a possible tonic effect on the endocrines may improve the patient's general health and indirectly ameliorate the symptoms.

The results obtained in these cases show that cancer cachexia was once temporarily checked, manic depressive insanity was definitely benefited in two cases, hypertension was once improved and twice the result remained in doubt. The rest of the cases were negative or doubtful.

In these cases, as well as in those of Table 1, the results cannot at all be compared with those cases where some form of senility has been the only or the principal indication.

In this paper I have abstained from giving an endocrine interpretation or classification of each patient, since a reliable endocrine study could have been made only in too few of the cases. A clinic would be of great service, where not only more complete observations could be made, but where also, as a matter of routine, complete blood counts, basal metabolism readings, and other data, could be taken in every case. The latter should be especially valuable in determining the influence of the improved gonadal activity on the thyroid function. I would also recommend a semen examination in every case. But in spite of the great shortcomings of the present article, of which I am well aware, the results unquestionably form quite a striking evidence of the definite clinical value of Steinach's discovery for the retardation of age.

I also believe that I have succeeded in dispelling the idea still being put forth in various publications, that the benefits are of only temporary nature. In

some cases of impotence they are, and naturally, in cancer also. But in senility (the principal indication), the results are decidedly lasting, more so than after any other form of treatment, or through autosuggestion. The latter has often been claimed in the Steinach operation as explaining the results, and it surely plays a part in a number of cases. However, to explain every good result by autosuggestion is preposterous.

The average time, after which the first improvements were noticed, was about six weeks. These were the improvements in general health, which lasted or gradually increased in such a way that sometimes the patient was better in the second year than he was in the first year after the operation (vide Case 57). Sexual stimulation in the form of spontaneous erections was frequently observed during the night following the operation. After a few days their intensity subsided and only gradually reappeared together with the beginning of the general improvement.

A number of patients have died: one from an accident, one from pneumonia, one, or possibly two, from cancer (in one, cancer had been the indication for the operation), and three others of unknown causes. However, no conclusions can be based on these deaths, Nothing has ever been asserted for the Steinach operation that these cases could disprove. No evidence exists to even suspect in any one of these cases that death has occurred propter hoc and not post hoc, and we must consider the fact that we are dealing almost exclusively with patients of a more or less advanced age, where death is *eo ipso* a greater possibility.

A few concluding remarks regarding the type of men who underwent the operation for the purpose of retarding their age:

Among seventy-five men there were nine physicians and dentists, six authors and writers, eleven other professional men, such as college professors, teachers and lawyers, four musicians, twenty-three businessmen, nine clerks and officials, six artisans and seven laborers and mechanics. This shows that the intelligent class predominates by far.

From numerous other quarters, as mentioned above, striking results similar to mine have been reported, and yet the Steinach operation is still being looked upon by the medical profession in general as a "fad" (if not worse), and as not deserving serious consideration. It is a regrettable fact that we have in our profession reactionaries, monarchists and fundamentalists, who are constantly impeding progress by assuming an overcritical attitude towards everything new. Dr. Sajous was right when he said in one of his recent lectures on endocrinology (not literally, but in sense) that we must often have and follow some intuition in the practice of medicine in order to make headway.[1]

No intuition is needed to realize the value of vasoligation, but an unbiased and practical, and not a narrow, one track, laboratory mind, in order to recognize and admit this value.

Naturally, we also have the other extreme. We have the faddist and overenthusiasts, who in honest conviction sometimes go beyond the limits of conservative criticism. And furthermore, there are the quacks and charlatans trying to grow rich through rejuvenation treatments. They naturally arouse suspicion and legitimate attacks, but unfortunately also unjust opposition against the method itself. The Steinach operation is no cureall, no wonder treatment, that will revolutionize medicine, but it has a definite value in balancing endocrine disturbances, relieving symptoms of age and prolonging efficiency—no more and no less.

For those who have had sufficient personal experience with the method (and Steinach's opponents hardly ever have), not the least doubt can exist that recognition will come to this discovery as it came to antisepsis and vaccination.

Within the limits of this article it is not possible to dwell upon the economic consequences that are bound to follow a general adoption of vasoligation. Likewise, the scope of this paper does not permit more than touching upon the aspect of an increased personal happiness accruing to the individual out of an improvement in his general state of health, with its possibilities for a renewed and widened sphere of activity. (Vide my cases 3, 8, 57, and others.)

CONCLUSIONS

The principal indication for the Steinach operation is premature or physiological old age.

In seventy-seven per cent. of the cases it has more or less definite, sometimes striking results in alleviating symptoms of senility, thus prolonging the active period of life.

These results can only be obtained if the correct technic is used and a definite indication insisted upon, and under these conditions the procedure is definitely harmless.

Where no reason exists to preserve the procreative ability of the patient, a bilateral operation is preferable.

The results are not only temporary, but can be pronounced as lasting several years.

Functional impotence is only an indication, a, when it is one of the symptoms of senility (then senility is the real indication); b, when endocrine gonadal deficiency can be assumed as a cause; c, as *ultima ratio,* after all other treatments have failed.

[1] At a recent meeting of a society for the advancement of the study of endocrinology, thirteen papers were read dealing with this specialty and not one discussed the function of the sex glands. Is it possible that the function of the testes and ovaries was not considered important enough? Or, are there other reasons for this omission? Gonadal functions could hardly be discussed without mentioning the rejuvenation experiments by transplantation, by vasoligation and by x ray treatments. A discussion of this work would naturally have attracted general interest, possibly—*horribile dictu*—newspaper comments. Was that to be prevented? Was secrecy and mystery to be upheld in the practice of medicine like in the middle age?

Indeed, several speakers proudly announced the fact during the meeting that newspapermen had left the hall in disgust since they understood nothing of what was going on—*Sapienti sat.*

Practical Therapeutics

RADIUM, THE ALLEVIATOR

WILLIAM L. HARRIS, M.D.
Providence, R. I.

As we look back along the path—often narrow, uncertain and tortuous—over which the science of medicine has traveled out of the mists which obscured its dawning up to the full noonday blaze of present accomplishment, we frequently smile at the conservatism—one is tempted to say "pigheaded obstinacy"—which in so many instances has barred the progress of what we now recognize as some of the greatest achievements of this science. The furious reaction against the teachings of Semmelweiss and Oliver Wendell Holmes as to the contagious nature of puerperal sepsis is a notable instance; the outcry concerning the commercialism of Morton, on account of which it was sought to prevent the use of surgical anesthesia, is another. Today we marvel that any physician who had it in his power to abolish the suffering of his patient under operation, could have withheld the agent of such relief because of the commercialism of the man who first brought that agent into general notice, but even yet, we are by no means wholly enfranchised from the shackles of conservatism of this kind, and there are still perfectly ethical and conscientious medical men who hesitate to ease the sufferings or perhaps actually prolong the life of a patient, by making use of an agent the value of which they personally regard as yet not fully proved.

At the outset we must, of course, admit that it is impossible to estimate the value of any new scientific principle, or a new application of an old one, until sufficient time has elapsed to permit generalization as to its merits. While it may not be necessary to await the verdict of posterity, it is nevertheless essential that we amass considerable data both for and against its efficacy before we can justly appreciate its actual worth. Such data must, in most instances, be collected by experiment, and this, even under the most favorable conditions, is a slow process. Therefore, the medical profession has heretofore been perfectly justified in holding back its unqualified approbation of the extended therapeutic use of such an innovation as radium. But today radium therapy is no longer in the experimental stage. Much as there still remains to be learned about it there is no doubt that at least some of its therapeutic properties are now well understood, and our knowledge of how to apply it to the best advantage has advanced far enough to be placed beyond the limit of guess work. New uses will undoubtedly be found for it, and better methods of application replace the ones now being employed, but what we have already gained is quite sufficient to advance radium therapy to a point where it can no longer be regarded as merely a medical fad.

There are a number of factors which have operated together to cast a certain disrepute upon radium therapy, and to create in the minds of cautious physicians—and likewise those of the less well informed laity—the impression that the actual facts do not justify the ofttimes extravagant statements which have been made in regard to radium cures. Many failures marked the beginnings of this therapy, perhaps more than the usual proportion which inevitably attends every essay into a wholly new and untried field, but mature consideration will frequently show that these failures were due to the use of preparations of the agent that were not properly standardized, were physically defective, or otherwise of inferior quality. Often, too, even when properly prepared radioactive substances were at hand, the quantity available was far too small to do the work required of it. It is now recognized that under certain conditions use of insufficient strength may induce conditions favorable to the progress of a malignant growth and, on the other hand, the destructive possibilities of too greatly concentrated or long continued radium doses, are so well known as to need no amplification here. It is evident that prejudice, thus quite justly incited, can only be overcome when radium therapy is controlled by accurate doses, and applied solely by those who have attained a high degree of technical skill, and the inevitable corollary to this is that initial special training must be followed by extended practical experience, for it is only those who have these qualifications who can be relied upon to administer the therapy to its highest usefulness. In careless or inexperienced hands, any such agent becomes potential of the greatest danger, and many disappointing or even disastrous results, which have served to cast discredit upon the therapy, should not be charged to the account of the radioactive agent, but to the inexperience of him who applied it.

Let him not be deceived by the apparent simplicity of the application! It is, in truth, simple to the skilled student of its properties, but woe betide those who believe its use presents no more difficulties than that of a new pattern of instrument, and proceed to apply it without proper preliminary training. The painful, often disastrous, and occasionally fatal results which ensue cast a shadow over the fair fame of radium therapy, and it is these unfortunate occurrences due to lack of skill and mature judgment and the prevalence of those "fools who rush in where angels fear to tread," which instill such fear into the minds of patients who might be benefited by the treatment that they are forever deprived of it. Should there not be everywhere established clinics where surgeons might go to study the practical application of radium, or to which they might send patients for treatment by those who were already fully competent, for if there is a remedy which—with or without operation—will abolish pain, prolong life, or at least somewhat stay the progress of the dread spectre, have we then the right to withhold this boon? Selfinterest and narrowness of view should not be permitted to stand in the way, nor the limited laboratory mind bar the gate to the comfort and greater happiness of the individual, and there should be a mighty campaign of education among members of the medical fraternity, if this is the only way to make receptive the minds of those surgeons who dread innovations and still persist in disregarding radium as a possible factor in the health salvation of their patients.

The surgeon everywhere should recognize that radium is not a rival to his especial branch of the healing art, but an auxiliary. As the late W. H. B. Aikins, of Toronto, once put it: "Its advocates do not claim that it supersedes surgery, but that it is a valuable adjunct to surgery in helping to prevent recurrence after operation, in rendering inoperable cases operable, and that it has proved itself to be one of the best palliatives we have in cases in which operation is impracticable, and in many of such cases has brought about apparent cure. This being so, it is obvious that in a large proportion of cases radium is used as a last resource, sometimes when the patients are in an almost moribund condition, and when all other measures have failed to give relief. This should, therefore, be taken into consideration in estimating the results. In such instances, even if we succeed only in alleviating the distressing symptoms and giving the patient a certain amount of comfort, the treatment will have justified itself, and radium will have accomplished what nothing else is capable of doing. The reputation of radium has too often suffered in the past, both at the hands of its friends and its enemies, exaggerated claims as to its efficacy being on the one hand based upon brilliant results in one or two apparently hopeless cases, while on the other hand it has been condemned altogether for isolated failures."

We have now reached that point where we have to ask ourselves whether, when a consensus of respectable opinion holds that radium can relieve the condition from which a given patient is suffering, we have any right to withhold that possibility of aid, even if our personal view may be partially or wholly skeptical. Has not every person suffering from conditions for which radium has proved of benefit an incalculable number of times, an inalienable right to such treatment, quite irrespective of whether he asks for it, or even knows of its existence? Does not this right exist, even in the presence of such ignorance, just as it is generally conceded that the unborn fetus has a right to life, even though it has no knowledge that it possesses life? And is not he who knowingly and without taking counsel of experts withholds this potential restorer of health and reliever of pain from the patient, quite as culpable as he who fails to make every effort to preserve the life of the unborn child, because in his unaided opinion there is little or no chance of its reaching term in a viable condition?

Many hindrances to the use of radium which existed until very recently have now been abolished. The available quantity of the element was not long ago so small that in many localities it was impossible to apply enough to obtain satisfactory results. In approximate figures France has nine and a half grams today, England possesses thirty grams, while here in the United States we have one hundred and twenty grams, distributed among private owners and hospitals. Neither can it any longer be argued that the cost of radium therapy is prohibitive, for though Italy and several other populous countries have no emanation plants, there is one in France, three in England, and at last accounts fully forty in this country. The perfection of the methods of collecting and handling radium emanation whereby the element may be retained in one spot while its emanation can be shipped safely and cheaply to a considerable distance, has so reduced the cost of radiotherapy that it is now within the reach of all, even those of moderate means, who, too poor to pay the fees applicable to the wealthy, but too well off and selfrespecting to derive any benefit from the amply equipped charity foundations which are freely open to the very indigent, are all too often shut out from the benefits of lifesaving measures which are always open to the two extremes of the social scale.

While the curative properties of radium are now established beyond all dispute, it is as a palliative that it still finds its greatest usefulness, and it seems on the whole rather strange that more attention is not paid—at least in literature—to this particular aspect of its application. Its ability to relieve hopeless conditions of the female breast and pelvis has found no counterpart in the entire history of medical practice. When Madame Curie began those studies, the results of which were to rewrite the whole story of cancer therapy, the sole measure of relief meted out to those unfortunates was the administration of narcotics in continuously larger doses. This only partially relieved the everincreasing suffering, and did nothing whatever to check the frequent hemorrhages or the evil smelling discharges from the brokendown cancerous tissue, which toward the last make the care of such a patient an almost unendurable task, rendering her obnoxious alike to herself and all about her.

Radium does away with all these distressing terminal phenomena; pain is greatly lessened or altogether ceases; hemorrhage is controlled; and the foul discharge abates and loses its disgusting odor. Often there is such marked relief of all symptoms that the patient will believe herself cured. No conscientious surgeon will encourage a patient or her family to be unduly hopeful, but there are on record numerous cases where growths which seemed almost at the utmost limit, have been so retarded that life has been indefinitely prolonged. In my own practice I have a patient who has been accustomed to take hunting trips with her husband. After a diagnosis of breast tumor which left no doubt of its malignancy and probable extension, radium applications were made at two month intervals, and under a heavy bombardment of well screened gamma rays the threatening infiltrating masses gradually disappeared, so that the patient was able to accompany her husband on what they believed to be their last trip together. The treatment was extended over a year and a half, there is still no sign of recurrence and a weight gain of sixteen pounds in the past six months. Two more "final trips" have been taken, and as yet the Grim Reaper is being held at bay. Thus may radium be truly termed the alleviator!

Of radium as an adjunct to surgery in the treatment of mammary carcinoma, much has been said and written, yet I feel that half the tale is still to be told. Experiments conducted at the Middlesex Hospital (England) have shown that "radium is able, at any rate in some cases, to arrest the advance of microscopic cells growing at the edge of the permeated lymphatics which form the advance guard of a carcinoma. The practical difficulties of giving an adequate dose of radium to every portion of an extensive growth are, however, enormous, and at present, insuperable, even when the growth starts

in an accessible situation. This depends upon the fact that the circle of permeation around a malignant growth may be very extensive." Yet, as has been impressively pointed out by Pfahler, in this country, "one of the advantages of radiation over surgery is that it can be used more extensively and can be used especially to surround the growth." Moreover, radiation treatment, as being practically painless, has a greater appeal to the patient—especially if it be a woman—than has surgery, and many who absolutely refuse operation at the outset may be persuaded to submit to it after a preliminary course of radiation.

Much, of course, remains to be determined regarding the best methods of applying this preoperative radiation. In a recent report of the British Medical Research Council attention is called to the wide variation in the practice of the different hospitals the work of which is summarized. "Whereas from the surgical point of view, it may be of the first importance that the most probable tracks along which the disease extends be given heavy doses of radiation, much depends from the radiologist's point of view upon how certainly these are known and how large a dose of radiation may be administered with safety to the several regions of the body which are being invaded." The report nevertheless concludes: "The encouraging feature of the data submitted is the endeavor which is being made to utilize radium fully as an aid to the surgical measures in cancer of the breast." One of our own radiologists, R. H. Boggs, once remarked that "Radiation for the treatment of cancer of the breast has been so changed by imbedding radium that where superficial skin effects were formerly produced, now cancerous tissue deeper than that which can be removed by the knife can be destroyed without opening the lymphatic chains." This author is of the opinion that if surgeons would uniformly give anteoperative treatment by imbedding radium, and remove less tissue, "thereby leaving the sclerosed lymphatic tissue as a barrier against cancer cells, the end results would be better, at least in the borderline cases; that is, there would be fewer recurrences, and if a recurrence did take place it would be considerably less than when the operation precedes radiation."

Of the value of postoperative radiotherapy in breast cancer and in recurrences there is now but little question; but lest there be some who still hesitate to give this added safeguard against speedy and terrible death to the patients who come to them seeking relief at their hands, I would add my plea to those which have already been uttered. Boggs makes the statement, backed by an impressive array of authorities, that when the axillary nodes are palpable there are very few cures by surgery alone without radiation, and when they are not palpable, but are found to contain cancer cells microscopically, only about twenty per cent. of the cases are cured at the end of five years. Greenough asserts that when the axillary glands are palpable twelve per cent. can be cured by operation, and Finsterer places the percentage at 4.3. Ewing believes the last figure represents the average of surgical success, which means that a woman who has a well established cancer of the breast with palpable axillary nodes, has one chance in twenty-five of being cured by operation. My own faith in the ability of radium to cope with postoperative recurrence is so great that I never hesitate to leave enough skin to cover the wound satisfactorily, even if it is evidently malignant, for as soon as the wound is healed, a bombardment of 2,000 or 3,000 mgr. hours of properly screened radium to the skin will quickly control the surface condition.

As an illustration of the value of radium as an adjunct to surgery I would cite a single case of my own, fairly typical of many such which have appeared. At the time of operation but one thought was entertained, namely, the possibility of postponing for a few months an inevitably fatal outcome, and during that period to reduce to a minimum the destructive process in the skin covering the left mammary region.

Case.—A woman, fifty-three years of age, the mother of seven children, had for twelve months before coming under my care noticed a mass in the left breast which increased in size steadily, and now showed involvement of the pectoral, axillary, supraclavicular and infraclavicular nodes. In the triangle indicated by the clavicle and outer border of the pectoralis major muscle and a line drawn perpendicularly through a point one inch to the left of the nipple, there were malignant indurations of the skin numbering eleven in all. One supraclavicular gland was the size of a large olive, and there were several smaller ones. At operation the axillary involvement was found to be so extensive that it was with difficulty that the nodes were detached from the axillary vein. Both pectoral muscles were also involved.

Following operation a seventy-two hour radium treatment was given, using one hundred mgs. of radium, screened with two mm. of brass, applied to the whole axillary region through a three quarter inch para rubber drainage tube introduced well into the apex of the axilla. The position of the radium was changed every twelve hours. Eight days later, into that portion of the anterior chest wall enclosed in the triangle above described one hundred and twenty seeds of radium emanation, small capillary tubes averaging a content of one third of a millicurie of radium emanation each, were implanted; and two weeks later, into the surrounding portion there was a second implantation of eighty seeds of the same strength. From February until August there were monthly treatments through both anterior and posterior axillary folds, to the supraclavicular and infraclavicular regions and along the anterior mediastinum, of three thousand milligram hours each. Up to the present there has been no return of the growth.

Concerning the radium treatment of those forms of carcinoma of the breast both primary and recurrent, where the surgeon can give no aid, this agent now holds out a hope of prolonged life and in not a few cases of clinical cure which has endured far beyond the arbitrarily established five year limit. At the Memorial Hospital in New York they regard as the best method of handling such cases external radiation by x rays, with a fifteen inch exposure, ten inch spark gap and twelve inch focal distance, with forty-four mm. aluminum filtration and four ma. of current. In conjunction with this they employ an implantation of bare radium emanation tubes into the growth, giving a complete dose at the first sitting. In tumors which are primarily inoperable especially, the use of the tiny capillary tubes of radium emana-

tion has proved most satisfactory. There is now on the market an improved implanter for these little seeds, which makes possible an even distribution of minute quantities of radium throughout the growth.

As an illustration, I will cite the apparently hopeless case of an Italian woman, for whom fifteen years ago nothing could have been done. Emanation seeds were implanted, an initial distribution of one hundred and twenty seeds in the chest wall, followed by a second distribution of eighty seeds in chest wall and axillary region. This was supplemented by three thousand hour treatments once a month for seven months, with the radium so applied that the mediastinal and axillary glands received most of the radiation. At the end of a few months there was no noticeable improvement in the condition, but the surgeon being absent for ten months, at the end of that time the patient again came to his office, looking the picture of health. She was entirely free from pain, and when the chest wall was examined the condition was ideal, there was not a sign of recurrence. Scattered throughout the whole area where the radium emanation treatment had been applied one could detect the round, shotlike nodules which collect about the little seeds.

Let us consider for a moment the effect of radium upon malignant tissue and its metastatic deposits. These considerations have received very extended attention from pathologists of high standing, notably Ewing and Schmitz in our own country, and Lazarus-Barlow in England. The last named recently made public the results of his examination of certain spheroidal celled carcinomata of the breast, which had been exposed to radium radiation and later amputated. One specimen received three radium applications before its operative removal.

"The effects of one exposure lasting five to six hours to the gamma radiations from five gm. of radium bromide are partly general and partly cellular. As general effects, it is noted that cellularity is somewhat considerable, that degenerated masses are rare, that millinucleated cells are very few, that fibrous tissue is present in considerable amount, is collagenic and a little fibrillar, that it shows no proliferation of connective tissue cells, that Indian file arrangement is very slight, and that small cell infiltration in advance of the growth is slight to moderate.

"In respect of the cells, it appears that the cells are large, that the quantity of cytoplasm is slightly hyaline or slightly granular, rarely vacuolated, but that frequently cytoplasm has disappeared entirely, leaving the nuclei naked. The nuclei are slightly variable in shape, more often contracted than swollen, and rarely are vesicular. Staining is faint or deep, but almost always is diffuse and rarely is irregular. Nucleoli are very uncommon; degenerated forms more advanced than ghosts are rare, but ghosts are fairly common. Mitosis is extremely uncommon."

Where there had been two radium exposures more cytoplasm are present in the cells, and it was more frequently hyaline and less frequently granular. The nuclei threads are more variable in shape, more concentrated and swollen forms are present, as well as many more vesicular forms. In general, it was noted that there was increased tendency toward the occurrence of localized degeneration of neoplastic cell masses, and that the connective tissue fibres permeating the growth become collageous in greater or less extent.

Ewing tells us that "ideal radium therapy seems to require a nice adjustment of relations between destructive effect on tumor cells and stimulation of stroma cells. Opinions differ as to whether the action is mainly on the nucleus or on the cytoplasm, but it undoubtedly affects both, and probably in variable degree." He has concluded from his observations that radiation is capable of restraining the growth of tumor cells without causing either autolysis or necrosis, and of transforming functionless, lawless cell growth into more organized and functionating tissues. He has also become convinced that the clinical results which we observe after radiotherapy are not usually due to the lethal effects of the rays, but are generally brought about indirectly, and mainly by interference with the circulation. Tumors thus radiated "exhibit isolated foci of necrotic cells, marked hydropic degeneration of collagen fibrils, but usually some areas in which the cells appear well nourished and viable. After several weeks sclerosis of injured bloodvessels appears, which shuts off the circulation. The tumor tissue then undergoes progressive fibrosis, but often groups of tumor cells persist in the scar tissue, from which metastases later take their rise." On account of the extremely variable anatomical and clinical character of mammary carcinoma, the difficulty of diagnosis, the danger of disseminating the disease by surgical manipulation, the extent of the radical operation and the frequency of recurrence, Ewing believes that the combination of x ray and radium therapy is destined to very generally replace the surgery of mammary cancer. He adds, "this problem must be worked out on selected cases over a long period and the answer seems likely to come from European sources before we in America are prepared to accept it."

These are impressive sentiments coming from perhaps our foremost authority upon neoplastic diseases. Though few surgeons are as yet willing to feel that their ability to cope with mammary cancer will no longer be called into play, I feel convinced that a wider recognition of the great field of usefulness which radiation has in connection with surgery, and its immense usefulness in those cases for which surgery can do nothing, will do much to advance us on the way to the mastery of this most frightful source of mortality among the women of our country. Let us not be behind Europe in making the greatest possible use, in whatever form it can best serve us, of radium, the alleviator.

Preventive Orthopedics*

REGINALD H. SAYRE, M.D.
New York

When Andry defined orthopedics as the art of preventing and correcting deformities in children, he struck the keynote of the intelligent treatment not only in deformities but in everything which pertains to health. In almost every ailment nature hangs out danger signals notifying us to stop, look, and listen, before trouble comes, and if we heed these warnings a great many of the maladies which affect us can be prevented, and in no branch of medical science is this truer than in orthopedic surgery. The majority of the patients who come to the orthopedic surgeon ask to be relieved of deformities which he is powerless to do more than to correct partially, but which would never have taken place had the first onset of disease been noted and treatment instituted to prevent the occurrence of the deformity.

Rickets is one of the most prevalent causes of deformity. Knock knees, bowlegs, anterior curved shins, coxa vara, and lateral curvature of the spine, are among the more prominent malformations caused by rickets, but it is exceptional for these conditions to be present at birth, and intelligent observation of the baby will usually show before the occurrence of the deformity, that rickets is present. Little beads of perspiration around the roots of the hair bordering the forehead, especially when the child is sleeping, at times so profuse as to make a wet place on the pillow where the child's head rests, should arouse suspicion. Failure of the fontanelle to close at the normal time, especially if the head is abnormally large in circumference, should always put one on guard, and if the child is slow in crawling, and prefers to sit on the ground and bump itself about, progressing backwards instead of forwards, look it over carefully and see whether the epiphyses at the wrists and ankles are bulging, if the costosternal articulations are forming a rachitic rosary, and investigate the child's diet and the amount of fresh air and sunshine it is receiving, and be careful it does not assume attitudes which may tend to produce bony deformities. If the child sits on its mother's lap with its legs projecting, the weight of its feet may cause anterior curved shins, or when it sits on a chair in a similar position the same deformity may occur (Fig. 1). If the child sits on the floor with its legs crossed like a tailor, bowlegs may be produced, while if it sits with its knees together and its feet stretched out at each side, knock knee is apt to result (Fig. 2); if the child is carried constantly on one arm by its mother, supporting itself with its hands around the mother's neck, a scoliosis is frequently to be noticed (Fig. 3). Attention to the general nutrition of the child and the evidence of improper posture may save a deformity, which, left to pursue its own way may become irremediable, but which if noticed before it has made marked progress can be easily corrected.

As mothers usually carry their children on their left arm right dorsal scoliosis is much more common than left dorsal, and in a number of cases of left dorsal scoliosis I have found on inquiry that the mothers had been accustomed to carry their babies on their right arm.

Sometimes the stiff ankle shoes which are used to hold the feet of rachitic children cause a sharp bend in the leg just at the top of the shoe unless measures are taken to correct the rickets (Fig. 4).

Improper posture is a prevalent cause of orthopedic deformities, and just as it is necessary to secure a good foundation before building a skyscraper, it is necessary to secure a good foundation if we wish to secure correct posture. Fashion makes most of us stand and walk with our toes turned out in a position which does not lend itself to security, and which, persisted in, in growing children with soft cartilaginous bones and easily stretched ligaments and muscles, may lead to structural changes in the shape of the bones of the tarsus which will eventually cause painful and weak flatfeet. Children are frequently brought to the family physician because the mother notices the child toes in, and asks him to correct this deformity. Careful examination will frequently show that the child is rachitic and that its intoeing is the results of its instinct which causes it to place its feet in a position to relieve the arch of strain and make itself comfortable, and no effort should be made to force these children by specially constructed shoes to turn their toes out,

*Read as part of a symposium on health examinations, presented under the auspices of the Medical Society of the County of New York and the New York Academy of Medicine, January 6, 1925.

but efforts should be made instead, to correct their general malnutrition and render their tissues firm enough to resist the strain. It not infrequently happens that these children when sent to dancing school are held up to ridicule by the dancing teacher and pointed out to the other children in the class as examples of clumsiness, and compelled to walk with their toes turned out, the result of which is to break down their arch, give them painful and feeble feet and cause them once more to seek medical advice. A great many adults do not realize that they are standing with their feet turned too far out, and should be taught to hold them in correct position before they acquire chronic tarsal sprain, which may give them very great disability (Figs. 5 and 6).

In these cases of outward deviation of the foot the Achilles tendon should be examined to see if it is too short, as, if it is, it will be found impossible to correct the valgus until the origin and insertion of the gastrocnemius muscle have been approximated by flexing the knee. With the knee flexed it will be possible to lower the tip of the os calcis and raise the front part of the foot by motion through the ankle joint, with the knee straight the os calcis cannot descend and the front part of the foot is raised by motion in the mediotarsal joint and a flatfoot will result.

FAULTY CARRIAGE

Patients who come to you for examination as to their physical condition should be stripped for examination as a great many mistakes in diagnosis are made as the result of failure to observe conditions which are plainly evident to the trained eye. Many children, and many adults also, stand with the back too much swayed, the abdomen protruding, and the chest caved in, the neck being poked too much forward. The majority of people do not know how to stand, or realize the difference in their general wellbeing which will accompany voluntary muscular effort to hold the body in a correct position during their ordinary occupations. Many gastrointestinal complaints are alleged by the internist to be due to visceroptosis, which is said to be the price we pay for walking on our feet instead of on all fours, but if we stand on our feet as we should, and flatten our backs as we should, throw forward the chest and pull back the nape of the neck, the ptosis of the viscera will be corrected. In a vast majority of instances people must be told that they hold themselves upright with their belly muscles as well as their back muscles, and instructed how to hold themselves in a good position.

In a great many of our schools the children are taught very faulty carriage in the effort to correct round shoulders. Instead of being taught to draw back the nape of the neck and lift up the ribs while the shoulders droop and the scapulæ slide forward, they are taught to pull the scapulæ together towards the spine and hunch their shoulders as near their ears as possible. Exercising once or twice a week in the doctor's office or in the gymnasium will not give correct carriage, and it is very essential that the interest of the patient should be aroused, and after he has been shown in the looking glass the difference between correct and incorrect posture, he should be encouraged once an hour throughout the day to hold the body so that he feels the muscles

FIG. 5.—Flatfoot and round shoulders, due to lack of muscular tone as seen in the adult. This shows the chronic tarsal sprain. The feet are turned too far out.

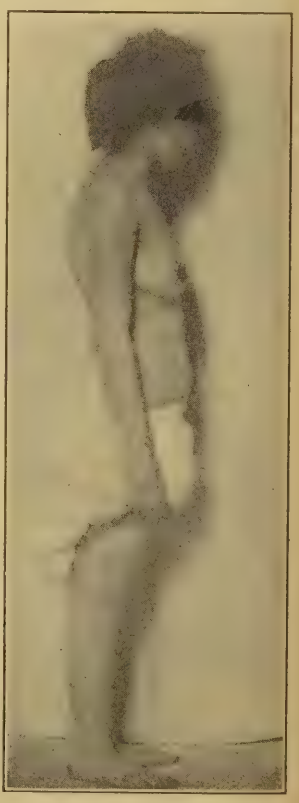

FIG. 6.—Flatfoot and round shoulders, due to lack of muscular tone.

making the same tension which he has seen with his eyes in the looking glass gives him a straight position, and if these exercises are carried out once an hour while he counts a hundred to himself, enormous good can be accomplished.

I am in the habit of telling such patients that if they will devote as much time to getting their backs straight as Paderewski did to exercising his fingers, they will achieve their object, but if they simply stand straight at the doctor's and at the gymnasium, and slouch the rest of the time, that nothing will happen.

IMPORTANT SYMPTOMS

Slight deviation from the normal in growing children may be the precursor of hideous deformity, and it is of the utmost importance that these slight postural defects should not be treated as trifling affairs but corrected before harm is done.

Inequalities in length of the legs should be noted. and if of any great degree, corrected by arranging the shoe so that the pelvis is straight, as otherwise bad lateral curvature may develop. Some of the worst cases of lateral curvature that I have seen have had such trifling deformity when the parent first suspected that something was wrong, that they have been told there was no need of doing anything for the child. Inquiry should be made as to the occurrence of what are often called growing pains, as these frequently mean inflammation of the joints. If a child complains of stomachache he may have a beginning spinal tuberculosis, and the mode of walking should be carefully noted to see if there is a careful, tender tread, if there is any lack of flexibility of the spine in bending or twisting, and if the mother says it gets tired when it walks, and wants to drag on her hand (Figs. 9, 10 and 11).

If it complains of pain in its foot or in the knee, and yet the foot and the knee appear to be normal, examine the hip with great care and see if these pains are not the reflex signal of inflammation in the hip joint transmitted to the knee or toe by the means of the obturator or sciatic nerve. As we get further up the child's body in noting its posture, observe the position of the head, see whether it cants its head to one side, and find out whether the head is held in this position on account of some ocular imperfection or disturbance of hearing, or whether there is a history of a previous sore throat, tonsillitis, or middle ear inflammation, which may have caused a metastasis in the upper cervical spine which may give rise to occipital headache, or pain in rotating the neck.

INSPECTION OF TEETH

Inspection of the teeth of these children is of great importance and may throw light on their malnutrition and general lack of resistance. There may be typical Hutchinson teeth, but in a good many cases of congenital syphilis we see irregularities of the teeth, gaps between the teeth, and disturbance in the enamel, although the typical crescentic peg shaped teeth of Hutchinson are absent. The Wassermann reaction in these children is often negative, while a positive reaction is obtained on examining the blood of the parents, and this should always be made (Fig. 12).

The Ear, Nose, and Throat

DANIEL S. DOUGHERTY, M.D.
NEW YORK

The limits of this paper make it necessary to presuppose that the practitioner is familiar with instruments and methods of examination and with normal appearances. It might be well, however, to call attention to some of the more important structural and pathological changes that indicate the possibility of future systemic affection. We must also stress the importance of obtaining an accurate history of the case.

In examining an ear, we first inspect the canal wall for evidences of infection such as acute cellulitis or furunculosis and then carefully observe the drum membrane. Is the drum normal in color? Is it retracted or bulging? Is it intact or perforated? If perforated, are there any signs of a discharge, or granulations, or of polyps? In suppurative cases the history of the discharge must be taken into consideration. How long has it existed? Is it continuous or intermittent? What is its bacteriology? Functional tests are not absolutely necessary as they have but an indirect bearing upon our subject.

In examining the nose, find out whether your patient has a history of mouth breathing; what obstructions there are in the nose; whether there is a deviation of the septum; whether there are hypertrophies of the turbinates; in short, whether there is anything that would obstruct the channel of respiration. Also note whether there is any discharge or scabbing present, and if there are any erosions or ulcerations of the septum or ecchymotic spots on the mucous membranes of the turbinates.

Remember that the mucous membrane lining the nose continues into the rhinopharynx and larynx, and that all infections or catarrhal inflammations may be extended through the continuity of that membrane.

In examining the mouth, take particular notice of the color of the mucous membrane. Extreme pallor of the membrane of the roof of the mouth, of the pharynx, or of the larynx is often indicative of incipient pulmonary tuberculosis. The presence of erosions or ulcerations may indicate tuberculosis or syphilis.

Inspect the condition of the tonsils. Are they hypertrophied? Are they the seat of any inflammation? Are they cryptic? Draw aside the anterior pillar and press the tonsil slightly to discover if there is any secretion and, if possible, have a smear and culture made.

In examining the larynx pay particular attention to the color of the cords and their movements of abduction, adduction, and tension. Observe carefully whether there is any infiltration of the membrane, ulcerations, or neoplasms. Here again infiltration or ulceration may be indicative of tuberculosis and syphilis.

Of all the subdivisions of the general system of medicine, no one is more closely allied to the others collectively and individually than that of rhinology, laryngology, and otology. A doctor making a periodical health examination must consider the condition of the nose, throat and ear.

Many conditions and symptoms observed in this tract are but local manifestations of general systemic disturbances, and may be of great significant interest in the diagnosis and prognosis of disease. They may cause disturbances elsewhere in the body. They may be prodromal or indications of an incipient or a latent stage of disease; or may complicate an active disease. A great number of symptoms of reflex origin may arise from abnormalities in, or perversion of, the functions of the nose and throat.

Let us briefly consider those local conditions which should influence us in the expression of an opinion of the health of those who may present themselves for examination, and then dwell for a moment or two upon some of the more significant symptoms relating to systemic conditions.

FOCAL INFECTIONS

The nose and throat are well known sites of focal infections which are likely to lead to socalled rheumatism, heart disease, kidney infections, and other crippling conditions. The discovery of sinus infections, cryptic tonsils, or other inflammatory conditions of the nose or the throat is an indication for a careful inquiry into the client's history of rheumatism or other general disturbance remote from the nose and throat. On the other hand, the existence of rheumatism, endocarditis, or other chronic condition of the joints or heart is a plain indication for a searching examination of the nasopharyngeal region.

Serious focal infections may exist without giving discomforting symptoms which drive the health client to his physician for relief. One of the greatest benefits of a periodical health examination is that the physician often discovers serious conditions which have not produced discomfort in the place of their origin.

It is also true that annoying symptoms whose site seem to be the nose and throat are really caused by disturbances elsewhere in the body. We will consider the interpretation of the three common symptoms: Cough, hoarseness, and nose bleed.

Cough.—The most frequently occurring symptom common to both general medicine and the specialty under discussion is cough,—and no symptom is more deceiving as to its origin. Cough usually arises from causes in the chest, trachea, larynx, or nose, but it may also be due to systemic disease or remote local irritations. A cough is caused by stimulation of the sensory fibres of the vagus distributed to the larynx and trachea. This free distribution of the nerves, together with the intimate connection of the vagus, the glossopharyngeal, and the cervical plexus of the sympathetic, indicates why excitation of pneumogastric fibres in any of its terminal branches may give rise to reflexes and explains the rationale of reflex cough. As an illustration of this, the night cough of children, almost invariably due to nasal or postnasal irritation, may be cited.

The sensory nerves of the nose are derived from the trifacial, the external portion being supplied from the first division, through the anterior ethmoid, and the posterior portion from the nasal branches of the second division, and a branch of the dental from the third. Irritation of the terminal filaments causes the impulse to be conveyed toward the centre and thence toward the periphery by the vagus.

VARIETIES OF COUGH

The reflex cough of nasal origin may be caused by any contact with the mucous membranes, particularly the hypersensitive spot in the nasal chamber near the anterior tip of the middle turbinate. Nasal vasomotor disturbances also excite cough.

Rhinorrhea and acute antral sinusitis may produce a slow, hacking, painfully persistent cough from the constant postnasal dripping.

In children, a reflex cough from nasal lesions is rarely present, but is often due to the presence of adenoids or follicular nodes on the posterior pharyngeal wall.

Nasal reflex cough is confined almost exclusively to persons of a nervous disposition. The cough of nasal or postnasal obstruction is necessarily aggravated by the consequent mouthbreathing. When postnasal it is of a hacking, irritating variety, as though attempting to get relief from accumulated mucus.

An elongated or acutely inflamed uvula produces a persistent, dry tickling cough, augmented in the reclining position.

The lingual tonsil causes an intermittent short hack, as though clearing the throat, which is due to accumulation of secretions in the glossal epiglotidian fossa and irritation of the epiglottis by contact.

Pharyngeal cough is usually occasioned by the presence of secretions and by irritation of the peripheral nerve filaments in acute and chronic inflammations, and by ulcerations,—the latter being usually specific or tuberculous. Paralysis of the pharyngeal muscles may cause cough from food irritation.

Hypertrophied tonsils, by pressure on the phrenic and recurrent nerves, may produce reflex cough, which is more pronounced at night. A cough may accompany follicular tonsillitis. Reflex coughs can also arise from the presence of foreign bodies in the tonsillar crypts, or between the tonsil and the posterior pillar.

Intrinsic laryngeal coughs may be produced by local irritation, as from foreign bodies and neoplasms of the vocal cords, or by local inflammation.

The croupy cough of spasmodic laryngitis is familiar to all, and is frequently caused by the presence of lymphoid masses in the nasopharynx. The cough may be due to foreign bodies, or neoplasms on the cords.

In the neurasthenic and hysterical, laryngeal neurosis often complicates the general condition, giving rise to the short, socalled nervous cough.

A dry, yelping cough is sometimes indicative of laryngeal chorea, which may or may not be accompanying a similar systemic condition.

Stimulation of the filaments of the vagus distributed to the stomach, the existence of tapeworm, or the presence of gallstones, may be the cause of reflex cough. It may also accompany cardiac disease, nephritis, or disturbances of the genitourinary tract.

Cough may mean the presence of an aneurysm, an enlarged bronchial gland acting through pressure, or even indicate impacted cerumen in the external auditory canal, acting through the auditory branch of the pneumogastric. Stimulation of the peripheral nerves of the skin may produce it.

A short dry cough may be an indication of basilar meningitis, or abscess, or a tumor of the cerebellum. At puberty girls of an unbalanced nervous system frequently suffer from a deceiving reflex cough.

Hoarseness.—Under this general title we may class, for practical purposes, all changes in the natural voice from a slight vocal weakness to complete aphonia. According to its causative factor, this symptom may be of little consequence, or may signify changes of great importance. A due regard to those possibilities will in every instance be of assistance in diagnosis and prognosis.

While it would be absurd to assert that exact diagnosis of a disease could be made from the character of the voice, there are many conditions that the trained ear may recognize through voice alteration. A comprehensive study of the voice in relation to disease would be interesting but too exhaustive for the limits of this paper, and we can only review briefly those causes of hoarseness observed in common practice. Neither are local laryngeal affectations, as topical inflammations, neoplasms, and other conditions, strictly within our province.

Hoarseness may arise from any cause that directly or indirectly affects the functional or structural properties of the larynx, or that modifies in any way the resonant qualities of the voice.

Resonance is derived from the nasal chambers, the nasopharynx, the accessory sinuses, and the pharynx. Any diseased condition of these would, therefore, serve as a modifying cause, and hoarseness is a constant and important symptom of such conditions.

Tonsillar hypertrophies interfering with resonance and the mobility of the parts, and also interfering with and altering their vascular supply, give a muffled tone to the voice. The same change is noticed in peritonsillar affections and in inflamed conditions of the soft palate, a function of which is to act as a valve regulating the amount of air entering the mouth through the oropharynx. The voice in cleft palate is of similar tone.

All nasal and postnasal obstructions occasion the same lack of resonance, giving rise to a dull monotonous voice. These causes also act indirectly through the accompanying mouth breathing, occasioning laryngeal irritation and consequent inflammation. Lingual hypertrophies produce hoarseness through irritation.

Diseases of the pharynx produce hoarseness by diminishing the lumen of that part of the respiratory tract, as in the husky voice of clergyman's sore throat, a condition sometimes called throat tire.

In all cases of hoarseness, the influence of climate, occupation and habit must be considered. Irritation from an unaccustomed air, working in dusty atmosphere or among vapors, excessive smoking or drinking are sources of irritation to the larynx. More especially is this remarked among mouth breathers.

Hoarseness complicates or accompanies many general diseases, among which we may mention tuberculosis, syphilis, typhoid, rheumatism, gout, diabetes, uncompensated valvular lesions, malaria, scurvy, purpura, chronic nephritis and hepatic cirrhosis, also disturbed vasomotor conditions. In some of these the hoarseness is the result of edema from venous stasis, as in chronic nephritis, cirrhosis, and cardiac insufficiency. In diseases of the heart and circulatory system, its significance is valueless as it occurs after the other symptoms have been well established. In nephritis it may precede all other symptoms. Hoarseness or aphonia with jaundice indicates cirrhosis, the symptoms being occasioned by local absorption of toxins.

In diabetes, hoarseness is at first dry and rasping, then of an ulcerative character. Hoarseness in malaria is of slight account. In scurvy and purpura it occurs from edematous conditions. In influenza, it usually results from catarrhal laryngitis, but may be serious, showing laryngitis hemorrhagica. In smallpox, measles and scarlet fever it is from catarrhal changes. Hoarseness in a rheumatic or gouty subject will generally disappear under constitutional treatment, but it may indicate laryngeal edema. Sudden hoarseness in uremia is serious, pointing to hemorrhage. A decided change of voice in croupous pneumonia may be the result of ulceration in the larynx. In herpes and in pemphigus, this symptom indicates an invasion of the larynx.

Hoarseness in syphilis and tuberculosis is common, and its significance universally recognized. The voice in syphilitic laryngitis is of a peculiar, painful, indescribable but characteristic intonation. A point to remember in suspected syphilitic hoarseness is that in some subjects hoarseness can also be produced by the use of potassium iodide.

The change in the voice is frequently the first noticeable symptom in tuberculosis, the larynx showing signs of the disease in its incipiency.

Hoarseness in pregnant women requires immediate attention and examination of the larynx. A liability to tuberculous laryngitis seems to exist in many of these cases when the disease has been otherwise latent and the ulcerative process is rapidly progressive in destruction. Reflex hoarseness may also accompany pregnancy.

Arterial and ovarian disturbances and operations upon the generative organs may occasion reflex changes in the voice. The change at puberty is familiar, and is the result of a hyperæmic condition, as is also the hoarseness sometimes noticed in the menstrual periods.

The high, shrill voice of old age is due to ossification and loss of vibration.

Hoarseness occurring with buccal symptoms of lead poisoning will probably be found to be due to the poison. That following the appearance of a tumor in the mouth suggests actinomycosis.

In children continued hoarseness usually indicates adenoids, and its significance is accentuated when it is accompanied by numerous paroxysms of croup. This is especially true in rachitic children. It may also indicate papillomata, which, however, are frequently a product of mouth breathing.

Reflex spasms of coughing may also occur from the presence of seat worms.

Hoarseness in diphtheria is of deep significance as indicative of an extension of the diphtheritic membrane to the larynx. In cases convalescing from the disease, hoarseness indicates postdiphtheritic paralysis.

The superior laryngeal nerves supply sensation to the larynx and the inferior or recurrent laryngeal is the motor nerve for all the intrinsic muscles of the larynx. Hoarseness is occasionally produced by pressure upon the recurrent nerves by growth of the neck, esophagus, or mediastinum, by goitre, or specific gumma. Pleuritic adhesions and induration of the apex of the lung may give rise to disturbance of this character, being more likely to occur on the right side.

Pressure of an aneurysm of the aorta upon the left recurrent nerve is the most frequent cause of voice change in this class. The recurrent character of the hoarseness is often a point of differentiation between aneurysm and solid tumors, the pressure varying in aneurysm. It may be an aid in the diagnosis of the incipient stage of aneurysm. A metallic cough may be present with a hoarseness due to pressure.

The voice, of course, may be affected by lesions of the central nervous system.

Nosebleed.—Nosebleed may be due to trauma, pathological changes, vicarious hemorrhages or constitutional disturbances.

No case of nosebleed is too insignificant to be ignored, and an earnest effort should be made in every instance to ascertain the exact seat and cause of the hemorrhage.

The thin mucous membrane spread over the cartilaginous or bony surface and plentifully supplied with blood from the septal branch of the superior coronary artery renders the septum a favorite site for hemorrhage, and in fully ninety per cent. of the cases the bleeding is from the anterior inferior portion of the triangular cartilage—the locus Kussilbachi.

In grave disturbances of the circulatory system, the hemorrhage is more likely to be found in the lateral walls, generally in the folds covering the turbinate bodies.

Of trauma and morbid changes it is unnecessary to speak at length. They belong more especially to the domain of the rhinologist, and do not come within the scope of our discussion. In all catarrhal conditions of a congestive nature, local lesions may occasion hemorrhages. Spontaneous epistaxis, especially after blowing the nose, may occur in cases of plethora, scorbutus, purpura hemorrhagica, pernicious anemia and hemophilia. Disturbances of the circulatory system are common causes of epistaxis, as in cardiac diseases without compensation, and even with compensation on rise of arterial pressure. Venous stasis in mitral disease or in aortic insufficiency is another cause of this class. Cirrhosis of the liver, Bright's disease and chronic alcoholism may have nose bleed as a concomitant symptom. Vasomotor disturbances may also occasion nose bleed. Nosebleed in the aged, seemingly without cause, may be an indication of incipient arteriosclerosis,—a fact with important bearing in the treatment of aged patients. Epistaxis is often one of the premonitory symptoms of typhoid. If it occurs

late in the disease, it lends graveness to the prognosis. In the later stages of purpura, malignant disease, and diphtheria, it should also influence the prognosis. In scarlet fever and measles it indicates a severe type of infection. It sometimes occurs in malarial fevers.

Epistaxis occurring with inflammatory conditions of the nostrils may indicate fibrinous rhinitis or diphtheritic infection. In severe cases these hemorrhages may be dangerous. The epistaxis of syphilis and tuberculosis is due to local lesions. In young boys recurrent epistaxis may indicate masturbation. In children a unilateral hemorrhage mixed with a mucus discharge usually points to the presence of a foreign body. Epistaxis in children is often indicative of adenoids. Nasal hemorrhage is the commonest form of vicarious menstruation. It may attend other forms of sexual irritation, and is also a common symptom in hysterical women.

CHRONIC SUPPURATIVE OTITIS MEDIA

The chief and most dangerous complications of middle ear infections are infection of the brain and its membranes, of the intracranial sinuses, and of the jugular vein. The carotid artery is seldom affected. The immediate danger is involvement of the mastoid antrum and cells without which the others rarely occur. The usual paths of infection are through the blood and lymph channels, and by dehiscence of bone in necrotic areas. Infection of one of the sinuses of the jugular results in septic phlebitis, which may be accompanied by septic thrombi. The dura mater is commonly affected by direct perforation of the tegmen tympani, giving rise to extra or intradural abscesses, i. e., localized pachymeningitis or to general pachymeningitis. Leptomeningitis may ensue from extension of the infection to the pia mater or arachnoid, or the substance of the brain may be invaded with resultant formation of cerebral abscess.

General septicemia and pyemia may occur through the agency of suppurative otitis. Septic conditions, and pericarditis, septic pneumonia and pleurisy, abscess of the lungs, infarctions of the spleen or kidneys, metastatic abscesses of the joints are all conditions in which at times the primary infective cause can be traced to the middle ear. These disturbances are frequently negligently treated without reference to this casual factor. Arthritis and synovitis may likewise occur. Facial paralysis may result from necrosis of the fallopian canal.

Cases of somnolence, angina Ludovici, Jacksonian epilepsy, septic gastroenteritis, and of involvement of the gasserian ganglion have been reported as complicating chronic suppurative otitis. The liability of the inflammation being of tuberculous origin should not be forgotten. All cases of purulent otitis should be regarded as serious, remembering that the majority of nontraumatic cerebral and meningeal inflammations are of otitic origin and infectious in character.

CONCLUSION

In conclusion, let me emphasize the relative importance of special symptoms, however seemingly insignificant, to general disease, and impress the fact that occurring primarily in the routine of the general practitioner, upon him rests the responsibility for the serious conditions that may develop through failure of their early recognition and consequent neglect.

111 West Eighty-fifth Street.

Occupational Hazards—Fatigue, Work and Rest*

LOUIS I. HARRIS, M.D.

New York

In the brief space allotted to me I shall attempt to present hurriedly a variety of conditions that may be of interest in connection with the periodical health examination of men and women, and of children, too, from the viewpoint of the industrial background.

It seems to me that we should not limit our interest to preclinical signs in connection with periodical health examinations, because those who will come to us, will want not only a determination of the signs antedating disease or indicative of its approach, but they will rather wish us to serve as health accountants, so that they may have a record of their health assets and liabilities, and, projecting these against a background of past history and present occupation, obtain a forecast of the future. Every one is interested in prognosis particularly, and wishes an answer to the question, "To what extent will my physical assets and liabilities affect my future?"

I think that a word of caution as to the broader scope of periodical health examinations than is indicated by the phrase preclinical signs, is rather essential.

Susceptibility to various occupational diseases and occupational hazards varies, of course, very greatly. It depends entirely on the physical endowment inherited and acquired by different persons. I shall not lose myself in that discussion. In presenting a brief sketch of this subject I have attempted to follow as far as possible the sequence that would ordinarily be followed in the examination and the questioning of an applicant for a periodical health examination.

EYES

Among preclinical conditions in the eye which may be indicative of future trouble, nystagmus is encountered not infrequently among those working in dimly lighted places or those who work in constrained postures, and who assume an unnatural attitude in the course of their work. Take the coal miner, for example, he is often at work in an extremely unnatural posture, in what are usually dimly lighted places.

*Read as part of a symposium on health examinations, presented under the auspices of the Medical Society of the County of New York and the New York Academy of Medicine, February 3, 1925.

The constrained posture, and the strain upon the eye muscles in particular, are evidenced in a short time, if one is watchful, by a slight nystagmus—usually lateral.

With reference to other eye conditions, we have frequently the beginnings of cataract in those who work in close proximity to furnaces. Men who are employed as stokers in vessels, who work in steel mills, occasionally present evidence of an impairment of vision, due to a beginning cataract.

The corneal scars that appear in the eyes of stonecutters are not without a large measure of significance to a watchful clinical observer. A diminution in the acuity of vision that may be very considerable is noted in the stonecutters. The stonecutter employs a mechanical device that causes four hammers to oscillate in a perpendicular plane and thus chip off stone and smooth the surface; he uses a new lens in a special frame to protect his eyes. Often at the end of four hours' work a degree of frosting of the lenses used to protect the eyes occurs that is hardly believable. It is necessary among some stonecutters to renew lenses twice a day.

This must suffice to give a glimpse of some of the eye conditions encountered as a result of occupational influences. The effects of glaring or excessively dim lights should be more familiar than they actually are.

NERVOUS AND MENTAL CONDITIONS

We have a variety of nervous and mental conditions due to industrial factors whose etiology I shall only indicate in broad and general terms. Those that are due to fatigue are exceedingly difficult to detect. They have not received an adequate measure of appreciation even at the hands of neurologists. The appreciation of those mental and nervous conditions due to fatigue has apparently lagged behind the appreciation of other clinical conditions in industry. Professor Southard before his death had made a substantial contribution to the understanding of various forms of psychic trauma in industry.

Mental irritability, sluggishness, a fatigue that evidences itself by an increase in the number of industrial accidents between the hours of ten and eleven in the morning and again between three and four in the afternoon, at which time fatigue effects are at their worst—these are common phenomena to the industrial physician.

Fatigue is manifested not only in the increase in accidents, but in a variety of painful disorders—for example, the neuritis that is so familiar in the form of telegrapher's or typewriter's cramp, and a variety of disorders that cause painful affections or that impair the motions of joints or muscles.

Hurry, piecework, and overtime work, are important contributing factors. You will find a great deal more of fatigue effects among skilled workers than among the unskilled. If you go into a large jewelry establishment, you will find that those who are doing the highly skilled work and who must not only use their visual faculties to the utmost, but who are doing extremely responsible work, of a character in which mistakes may total up a considerable amount in damages, are the ones who are likely to register the greatest number of mental conditions that are decidedly indicative of beginning trouble, and which, if neglected, may go on to cause a serious mental or nervous disturbance.

EFFECT OF POISONS

Various poisons employed in industry may cause nervous disorders. For example, one of the earliest signs of mercury poisoning in those employed in a hatters' fur establishment, where nitrate of mercury is employed in the carroting of hats in the felting process, is erethism—socalled; that is, a great degree of irritability, a proneness to quarrelsomeness, and to excitability. That quarrelsomeness may be often regarded as merely a casual personal peculiarity, but to the sharp clinical observer it has a significance that is far greater, and may be the first sign of mercury poisoning.

With regard to the tremor that is encountered among workers who use mercury, a very slight tremor may be an indication of beginning mercury poisoning affecting the nervous system.

HEADACHE

Carbon bisulphide, used in degreasing processes, in extracting fats from various seeds, in connection with the vulcanization of rubber, is an exceedingly important poison nowadays, and it causes certain nervous symptoms in the very beginning which are telltale evidence of trouble that must be early taken into account, or one will have to reckon with serious consequences. The nervous symptoms in carbon bisulphide poisoning are principally a headache which is felt most intensely about the root of the nose and the vertex, which spreads out and over the temples and down toward the shoulder blades. It is a peculiar, characteristic pain, an exceedingly sharp pain.

The subsequent effects of carbon bisulphide in causing symptoms resembling delirium tremens, progressive asthenia, and other conditions, cannot be dwelt upon here.

There are a variety of other poisons which produce headache or nervous manifestations, notably lead. The milder form of headache produced by lead—is often passed off as insignificant and meaningless and yet it may be quite indicative of the beginning deleterious effects of lead.

The early recognition of lead poisoning is notable and conspicuous for its absence even in the most prominent industrial communities. That has been pointed out again and again as a lamentable feature in the practice of medicine. Lead poisoning often is recognized only when we have marked paralysis together with a lead line constipation and colic that are so pronounced that even those who are not initiated into the intimate details of this subject may recognize the presence of plumbism. The headache is one of the beginning symptoms and should be remembered.

Headache due to eyestrain as a result of poor lighting, as a result of speedy work, as a result of glare, is to be kept in mind.

A form of headache not encountered so much in this community, but met with quite frequently in a place where explosives are manufactured, is the nitroglycerin headache among workers who are using nitroglycerin in the manufacture of gunpowder, TNT, and other similar products. The workers have a headache which is most intense, and which, if passed by and ignored may cause serious effects of nitrate poisoning to develop. A host of volatile drugs may cause severe headache.

ANEMIA

The anemia that is encountered among workers may have an industrial background and is notably due to two or perhaps three outstanding factors; anemia is one of the earliest signs in lead poisoning, and is frequently unaccompanied by the lead line, for this is found only in twelve to fourteen per cent. of even pronounced cases of lead poisoning; in fact it is usually unaccompanied by colic, or other signs of lead poisoning. Anemia is one of the precursors, so to speak, of lead poisoning.

Another industrial hazard of increasing importance and worthy of considerable thought is carbon monoxide poisoning in garages and wherever there is combustion of gasoline, coke, wood coal, and similar products. The hazard of carbon monoxide exists in exact proportion as ventilation is poor, and bears a definite ratio to the amount of fuel or gasoline that is being burned.

Carbon monoxide will frequently cause either a headache (a persistent headache, unexplainable on any other ground) or a marked anemia, and I therefore call attention to carbon monoxide as a poison which should be considered with reference to any complaint of headache or anemia.

Poor ventilation, of course, and other unsanitary conditions as well, are conducive to anemic conditions. The dietary of the worker I dare hardly do more than suggest as having a very definite relation to the development of anemia and nutritional disturbance.

SKIN

The skin gives telltale evidence of a considerable number of industrial hazards that have to be borne in mind. Jaundice is found notably through the use or manufacture or handling of TNT—trinitrotoluene. That was more familiar and often encountered during the war. During the war, too, we encountered jaundice in connection with the varnishing or doping of airplane wings, where tetrachlorethane was employed to make the wings moistureproof. Both of those agents, trinitrotoluene and tetrachlorethane, have a tendency to produce jaundice by virtue of their destructive action on red blood cells.

Eczema as a skin condition is encountered in a multitude of industrial conditions. Turpentine stands out notably as an agent that produces either eczema or a fissured or bleeding skin. Aniline frequently causes eczema. I am not now considering the other effects of aniline; I am limiting myself to skin effects. The blueness and cyanosis which aniline produces is of course not a preclinical condition. I point out these skin conditions as indicative of more serious damage that these agents may do.

A variety of furs, particularly raccoon and fox skins, are likely to cause eczemas.

Paraphenylendiamine, which is employed in the manufacture of hair dyes, has caused a great many eczemas as well as constitutional effects. These are properly preclinical conditions, indicating the effects of certain dangerous agents, which, if ignored, will produce damaging effects upon more vital tissues.

Ulcers, boils, and skin infections are often encountered. Who is there that has gone into a factory where arsenic is being handled, either in the form of Paris green or some other form of arsenic, who has not seen deep ulcerations in the skin produced wherever unclean hands came in contact with parts that were sweated? Mercurial ulcers are encountered in ever some many workers who handle this poison and may properly constitute a preclinical condition, the sole indication of something more grave that mercury may do if you ignore the ulcerative condition.

Hydrofluoric acid, used so much in the making of etched glassware, is an important agent. The paronychias and onychias, the marked eczemas and boils, the corroding effects of hydrofluoric acid are distinctive.

Chromic acid, with its perforations of the skin, its perforations in fact of the septum of the nose—a painless perforation—has to be borne in mind.

NOSE, THROAT AND EARS

Affections of the nose and throat are marked in the hatters' fur establishments. One finds upon examination of the nose and throat, and the nose in particular, that it is obstructed by the accumulation of a great deal of fuzzy material which is flying about in the atmosphere, causing not only local effects, but sometimes affecting the eustachian tubes and ultimately, though indirectly, affecting hearing—an important thing. Of course, hearing is affected in some industries not only by dust and by local infections, but by the overwhelming noise element.

Some years ago, in talking under the auspices of the County Medical Society, I had occasion to report that over fifty per cent. of the workers in one establishment were affected with permanent deafness as a result of the indescribable and unbearable noises to which these individuals were subjected during the long hours of their work.

The affections of the voice will not detain me. I might allude to them briefly as being something that teachers complain of as a result of exposure to chalk and room dust.

MOUTH

The mouth has to be alluded to for a moment because there some important indications are to be had of impending disturbances of a grave character. It is not generally known, for example, that where one fails to get a lead line on the gums, one may be successful in finding upon a close examination of the buccal mucous membranes a small or large blue or slate colored area opposite the molar teeth, which is quite indicative of lead poisoning, when one has become accustomed to it. It may show the deposition of lead when a lead line may be absent, and may be the forerunner of more grave symptoms of lead poisoning.

In the mouth, too, there is a larger and more distinctly bluish discoloration that is encountered on the buccal mucous membrane among those who are manufacturing thermometers or barometers, or who are preparing hatters' fur. They aggregate thousands of workers who pass through our hands in clinics, hospitals, and private practice, and in whom we fail to recognize these conditions.

The telltale evidence of corrosion of the teeth is not so important in this vicinity. Around Niagara Falls that becomes exceedingly important, and is evidence of the effects of strong acids which are manufactured in enormous quantities.

One of the gentlemen present at this lecture called

my attention to a striking mouth condition some months ago. In the course of surgical work that he was doing he came across a marked case of necrosis of the jaw bone. I believe, if my memory serves me right, that this one surgeon encountered three such cases in a fairly brief period of time recently among those who had been handling phosphorus and who probably had ignored a carious tooth, which is known to be a very particular source of hazard to anybody exposed to phosphorus poisoning. The physician who examines a person who comes in contact with phosphorus must pay careful heed to caries of the teeth, aside from the importance of dental infections in many other connections.

There are many other industrial conditions which may affect the lungs, the gastrointestinal tract, the kidneys and many other organs which I have not the time to refer to even in brief and sketchy fashion. A number of these have an even greater significance to the clinician and the patient than those which I have described in the foregoing.

The examples which I have thus far cited will, I hope, indicate to you that there are a host of important clinical observations and data which have been slowly accumulated during recent decades that are a closed book, not only to the average physician but even clinicians who pride themselves on the breadth and scope of their reading and observation. If my brief catalogue of just a few of these clinical data with reference to the preclinical signs of diseases caused by occupational poisons or factors have piqued the curiosity and challenged the interest of any among my hearers, I may promise them with assurance that a more detailed study of the effects of occupational influences will richly reward them.

808 West End Avenue.

The Respiratory System

JAMES ALEXANDER MILLER, M.D.
New York

In the limited space at my disposal it will be impossible to cover the subject of the respiratory system, so I will not stick to my subject but rather, I think, restrict it to what I consider really the most important factor, the question of pulmonary tuberculosis.

We will touch on some of the other factors in the respiratory system, particularly chronic disease of the lungs, but what I shall have to say is mainly concerned with pulmonary tuberculosis. Also I shall not stick to the subject in the sense that we speak of preclinical signs of tuberculosis, because there are none. I do not know what is meant by the preclinical signs of tuberculosis. My idea of what we are after, as medical clinicians, is not to find out disease that does not yet exist, but to recognize the actual signs of disease, early or potential.

Our problem in the practice of medicine is so to extend the bounds of our knowledge that we become more expert in picking out pathological conditions before they have come to the degree of disability where the patients recognize that they are sick. A socalled health examination takes place usually because, for some reason or another, a person who considers himself well comes into the hands of the physician. This is quite different from the ordinary procedure by which we, as medical men, only see people when they think they are sick for some reason or another.

Many of the chronic diseases, of which tuberculosis is, I think, a good example, come on so insidiously many times that it is extremely difficult for the patient to say just when he passes over from being a well person into being a moderately or slightly ill person. Now it is up to the physician, it seems to me, to try to find out, wherever he has the opportunity, a little more accurately than we have in the past, just where this borderline is.

When we come to health examinations, I doubt if there is any one serious disease which we come across more unexpectedly—unexpectedly, I may say, to the patient you are examining—than pulmonary tuberculosis. For that reason I think that it is going to be extremely valuable, if properly applied, to have this general extension of examination to people who think they are well; whether it is done in groups, such as industrial groups, or whether it is done through an education of the community, which this movement has in mind, of getting people periodically to consult their own physicians.

When it comes to the examination of the chest, one is not going to find a great deal, in the majority of these cases, in the way of pathological evidence of disease, and unless we are going to be able to have our suspicions aroused by slight evidence of possible disease, we are never going to find these unsuspected cases of pulmonary tuberculosis, of which there are a great many at the present time in the community.

It is, therefore, it seems to me, not a question of preclinical signs of disease, but making the earliest possible diagnosis, which is our job in this particular field.

Tuberculosis is a big problem still. In spite of the progress which we have made in the prevention of the disease, it takes such a heavy toll in disease and death that I think it cannot and should not be absent at any time from the mind of an examiner, whether he be an insurance examiner, or a family physician, or an industrial physician, or a specialist. It is one of the very common diseases.

The family physician, I think, is in a particularly difficult position in regard to a disease of this kind, for the reason that he frequently knows his patient so well that he is likely not to notice the slight deviations from the normal, which a stranger sometimes will notice.

Also I think that the personal relations are such that the patient often comes to the physician more as

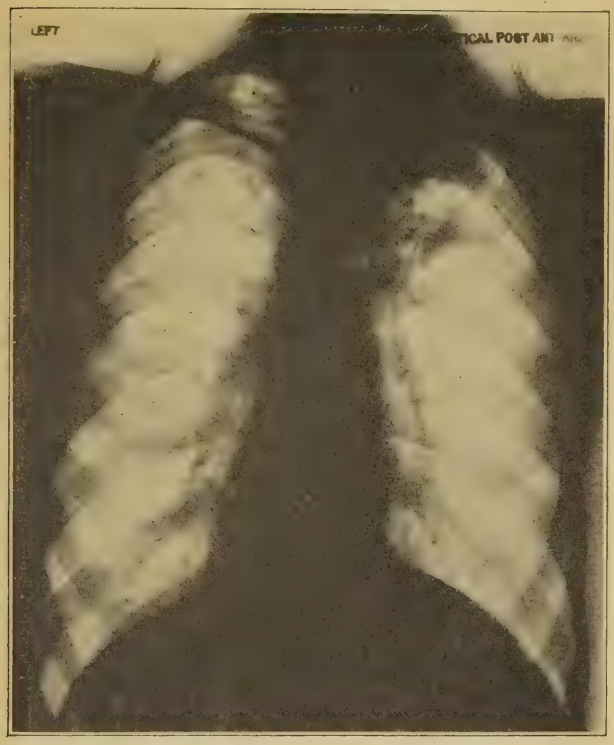

FIG. 1.—Definite tuberculous infiltration of the right apex. No physical signs.

a friend in rather a casual way and says, "There is not very much the matter with me, but I do not feel quite up to par," and that sort of casual contact leads to a rather casual investigation.

Tuberculosis, in its early stages, will never be discovered by any such method as that. Many and many a time we see in the sanatoria, where we have not only early but advanced cases of tuberculosis, dozens of cases, one after another, who have the same sad story to tell, that they, as they look back on it now, realize that they had the disease six months, a year or two years before it was recognized, and that during that time they have seen numerous physicians. This is not by any means always the fault of the physician. The patient often, intentionally or unintentionally, puts the physician off the track, but the fact is there nevertheless and the responsibility is a medical one.

We should not by any means consider that the early evidences of possible tuberculosis are confined to the chest. There are many other things which should excite our suspicion, and we would never find the condition in the chest unless such a suspicion is aroused. And I think we should approach this whole question of people who are perhaps a little but not much below par, with the possibility that tuberculosis is one of the great factors to be considered. I do not care whether you are speaking of the chest or whether you are speaking of some other organ, because tuberculosis is a systemic disease and not a local disease and one which finds its manifestation in practically all the organs of the body, but of course chiefly the lungs.

Now, what are the things that have in the past and are at the present time escaping the attention of the patient—or the prospective patient, because he does not always consider himself a patient—and the physician who sees him in various capacities, and may escape a rather careful investigation of the health examiner, that is, the person who is examining the patient who is presumably well? I believe that one of the great mistakes that we make in trying to recognize early disease of the lungs is the undue emphasis we place on the physical signs.

We begin as third year or second year medical students approaching the problem as one of physical diagnosis. I think we are biased from the inception of our contact with tuberculosis by that point of view. We make our diagnosis as early students on the physical side; we think of pathology in terms of the physical signs; and we think of tuberculosis as evidenced by physical signs, when as a matter of fact early tuberculosis will often, as I hope to be able to demonstrate to you by certain cases in my own experience, frequently show no physical signs at all, even when it is by no means incipient.

Certainly in this type of examination that we are considering you are not going to get, as a rule, much in the way of physical signs, and unless your suspicions are aroused to the possibility that there ought to be in such a case some abnormal physical signs, you are not going to make your diagnosis and save the patient at the inception of this infection.

The important thing, I think, for us to keep in mind is that tuberculosis, as it manifests itself clinically, has usually been preexistent for a long time without having any manifestations which have been recognized, but that if we find something in the individual patient which is somewhat suspicious, if we go back into the history, we will often be able to trace the path of that infection. In other words, tuberculosis as a chronic illness is not by any means a continuous illness. It manifests itself in what you might call a relapsing infection, with slight manifestations followed by periods of quiescence with no symptoms

FIG. 2.—Extensive disease of both upper lobes. Almost no physical signs.

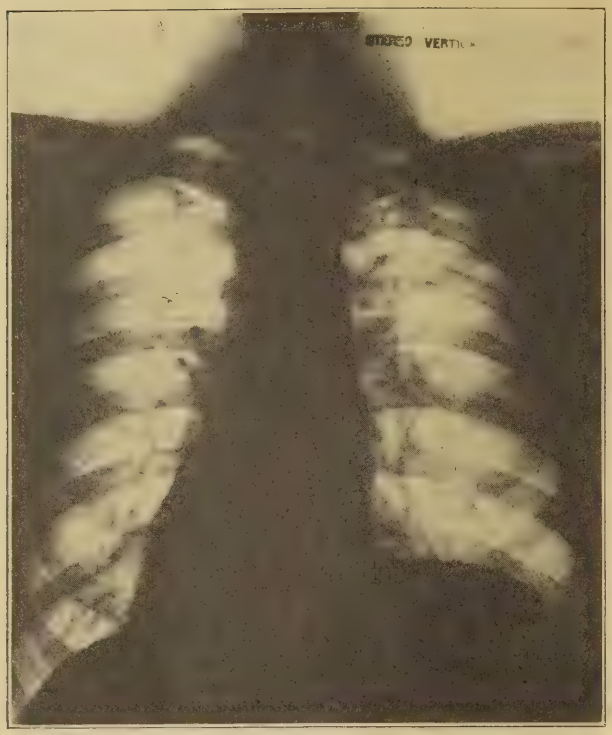

Fig. 3.—Marked lesion of the right upper lobe. Physical signs inconclusive.

over a long period of time, months or even years; then another exacerbation perhaps quite of a different sort than the first, and then finally the disease is recognized. Our problem is to try to catch that somewhere along the line much earlier than we are doing at present.

You take the patient who comes to you with definite cough, expectoration, fever, and physical signs; that patient will almost always have in his or her past history a story of a pleural effusion at some time or other, which was treated as such; a story of grippe which persisted with a cough for several weeks and then was cured; a story of malaria unexplained, over a period of weeks, with plasmodia never found in the blood; an ischiorectal abscess which was cured after a few weeks or months; a spitting of blood which was reported to the doctor, but because, as the patient will say, "I was in fine shape, and the doctor said that I was in fine shape, that blood came from the throat, and it must have because I never heard anything more from it."

Each one of those instances, or any or all of them, when it may be spread over eight or ten years, what does it mean? It means that the tuberculosis which you see and recognize today is the same tuberculosis that showed itself ten years ago in one or many of the manifestations—the pleural effusion, the grippe which persisted with a cough and then was cured, the malaria unexplained over a period of weeks, with nothing found in the blood, the ischiorectal abscess, or what not.

Our business is to pick up that clinical chain and make a complete examination—and we must pick it up before the patient comes to us with fever, loss in weight, cough, expectoration, and so forth, i. e., with advanced disease. One cannot go wrong in treating potentially as a case of tuberculosis, until proved otherwise, any case of definite, unexplained hemoptysis, any case of pleural effusion, any case of protracted cough for a month or so with or without physical signs, particularly if any of these have slight or only slight constitutional disturbance. Yet our experience seems to be that this is the last thing that is thought of. These little things come and last a week or two and then go, and we flatter ourselves into thinking that we have cured a patient of the grippe or malaria or pleurisy, or what not, and then it lies dormant and then comes up again, and when we see and make a diagnosis, we have an advanced case. That is simply due to our not having gumption enough to pick up the case when the evidences are so slight that the patient doesn't know he has anything serious; and we all do know that if we do pick them up, then the response is prompt and almost sure in the way of recovery.

Therefore, in any such case as that, it is extremely important to have a definite history, carefully elicited (and you will usually get the cooperation of the patient in this) by a suspicion aroused by something or other in the appearance, or something that you find, or something that they casually tell you in their story, which you pick out often with difficulty and get a disjointed story over a period of years which you must put together into a definite clinical picture; often your physical signs will bear it out, and sometimes they will not.

More important to my mind than the physical signs is not only this history connected up into a clinical picture, but the constitutional disturbance—slight malaise, slight fatigability, slight loss of weight, slight disturbance of digestion, slight irritability, with or without a little disturbance of afternoon temperature and rapid pulse. These are often more important in exciting your suspicion than are perhaps the

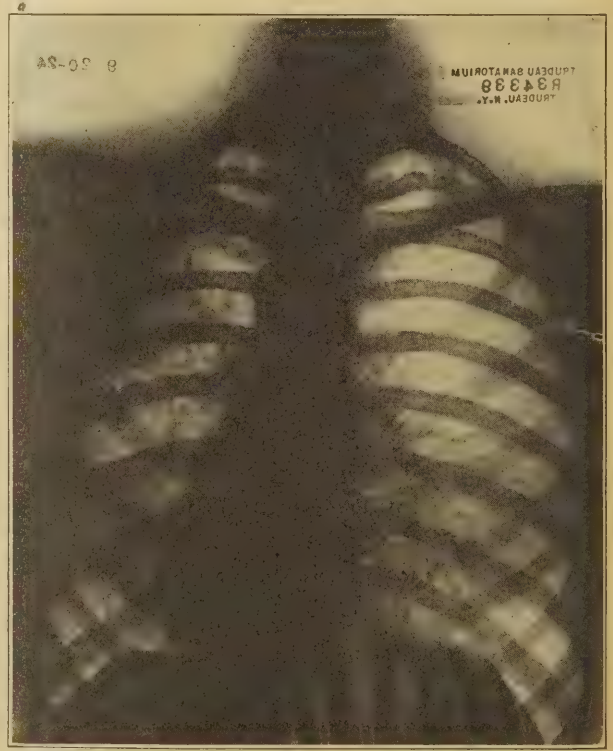

Fig. 4.—Extensive infiltration of the left lung. Very slight physical signs.

slight signs which may exist in the chest, which may perhaps very easily escape attention.

So that I want to urge, before speaking of the definite signs, the necessity that we, as medical men, should be more suspicious than we are of tuberculosis as a widespread disease and having that suspicion so constantly in our minds that we will be looking for this kind of story of which I have just given you the outline and for those kinds of slight symptoms which the patients will often make very light of, because they can work for months with that kind of a picture before they feel that they are even sick enough to go to a doctor.

The physical signs, I think, have been exaggerated in importance; so much so that I think if you turn to the student's medical textbooks and to our monographs on the early signs of pulmonary tuberculosis, most of us feel that that is really so complicated, the evidences are so slight, the importance of little deviations from the normal so great, that it is almost beyond us. As a matter of fact, there is nothing obscure in the physical signs of an early tuberculosis.

I think Dr. Lawrason Brown has done a very great service to the whole medical profession when he has simplified all this. He, as one of our leading specialists, instead of making the problem more complex (as a specialist is more likely to do) has simplified it greatly. In this respect he says, "There are five cardinal evidences of tuberculosis, which are present in practically every case, and if you were guided by them, you would not be more than five per cent. wrong." And what are these?

1. Positive sputum.
2. Definite hemoptysis.
3. Definite pleurisy with effusion.
4. Definite localized râles on coughing, above the level of the third rib, i. e., at the apex.
5. Definite x ray changes in that same area above the level of the third rib.

He says nothing about the slight changes of percussion, nothing about the lagging, or the muscle tone; nothing about these little changes which we have been taught are so essential. There they are, and he who runs may read; but some of us do not.

If every doctor could hear a râle that is in a chest and knew how to elicit it, he would not be long in making an early diagnosis. If we link up with that the fact that physical signs are often of little importance, and that the clinical signs are of more importance, we will make early diagnosis; at least, earlier than we are making at the present time.

The laboratory may help but the cases we are speaking of rarely have positive sputum. The tuberculin test is a thing we can use if we will, but it has no great value in adults. The same thing applies to the complement fixation test. The x ray is extremely important, and the thing is to know when you want an x ray. The thing you want to do is, when you have a case that is suspicious and you can not hear anything in the chest, if it is suspicious in any way, always have an x ray.

I am going to show you in just one moment some cases in which I was unable, even after going back after the x ray, to find anything abnormal in the physical examination. The thing is to have an x ray taken in suspicious cases, whether you hear anything or not.

Not all cases that have suspicious physical signs have actually tuberculosis. That is extremely important to remember. There are thousands of cases on the board of health books today that are healed tuberculosis, and, having once been put there, no one had the nerve to take them off. They heard some signs and they never had the courage to say that the first doctor was not right. In other words, the fact that a doctor can find the signs of previous tuberculosis doesn't mean they now have the disease. How can you tell? You watch that case and find if there are any clinical signs. There is no sense in sending a patient with râles for a few weeks to the Adirondacks simply because he presents signs of a previous tuberculosis. In other words, a healed tuberculosis will leave a scar which a competent examiner can find, and our job is to pick out those that are active and those that are not; and we must not do the injustice of making a case a positive active case of tuberculosis when it is simply an old healed, arrested case, evidences of which are often there without the patient knowing it.

Those are the main things, it seems to me, that we should keep in mind. There are dangers on both sides. There is danger, on the one hand, that we will let slip by the case that is tuberculous, and there is danger on the other hand that we will call a condition tuberculous in which after all the patient simply shows the evidences of a past infection.

Now, it needs all the commonsense we have, to steer a clear path before us, but it is a question of simple, ordinary clinical sense and commonsense, in which I should like to emphasize particularly that constitutional disturbance and the story of the patient is more important than the physical signs themselves; and that the x ray is an extremely important and valuable adjunct to the determination.

NONTUBERCULOUS CONDITIONS

There are many other conditions besides tuberculosis in the respiratory tract.

Since the influenza epidemic there have been many subacute and chronic infections of the chest which are localized, which closely simulate tuberculosis, but they do not show some of the things that tuberculosis generally does. In the first place, the physical signs are usually quite extensive. In the second place, they are almost always in the lower lobe instead of in the apex. In the third place, the sputum is often abundant and never contains tubercle bacilli. In the fourth place, the x ray shows almost nothing, while the same signs in pulmonary tuberculosis will show marked density of the lungs. We have all seen many cases diagnosed as tuberculosis that do not belong there at all. They have extensive physical signs and a constitutional reaction quite different from tuberculosis symptoms.

In connection with these health examinations, I should like to speak of tuberculosis carriers. They are usually those chronic fibroid cases often associated with emphysema and bronchitis, particularly in older people. Whenever we get an older person who is rather thin, with emphysema and bronchitis and winter cough, those are the persons to whom we refer as tuberculosis carriers. You often will find that those patient's sputum will be loaded with tubercle bacilli; yet they are not sick. There are many of these chronic patients going around, and from the

viewpoint of prophylaxis it is often important to pick those cases out.

I also want to speak of the importance of what Dr. Dougherty is going to bring up in connection with upper air passages, and that is that a lot of these conditions in the chest which are nontuberculous, that are chronic in nature, are often secondary and are dependent upon infections in the upper air passages and particularly in the sinuses; and that many of these conditions which bother us much will clear up if the upper air passages are properly taken care of; and in many and many a case of persistent bronchitis and persistent localized condition of the lower lobe, persistent peribronchitis will clear up when the sinuses are properly treated.

I have about eight or ten illustrations which will show what I have in mind in connection with the difficulty and importance of having x rays.

Case I (Fig. 1).—This patient came to me with a story of a slight cough for six months, no other symptoms. He came for examination because he wanted to be married and on that account thought he ought to be examined. A real health examination. He felt perfectly well and I found no abnormal physical signs but on account of his cough I had him x rayed. He showed definite tuberculous infiltration at the right apex. He took the cure and is today perfectly well and happily married.

Case II (Fig. 2).—This patient had stopped work a month before I saw him on account of persistent indigestion. He consulted a gastroenterologist and while under his care a slight cough developed. He was sent to me and the only abnormal physical sign that I could find was slight dullness at one apex. The x ray showed extensive disease in both upper lobes.

Case III (Fig. 3).—In this case the patient had a slight cough and expectoration for three months; no other symptoms. The physical signs were inconclusive but the x ray showed a definite lesion in the right upper lobe.

Case IV (Fig. 4).—This patient felt perfectly well and had had no cough, but the previous week had a marked hemoptysis. The only physical signs I could discover were a few râles in the left axilla, but note what the x ray showed—an extensive lesion with involvement of at least one half of the left lung.

The other slides showed much the same thing. That is, slight symptoms, few or no physical signs, but a definite x ray picture.

The lesson of all of these cases is that only an x ray will show up many of them and we must be alert to suspect that tuberculosis may be present and be prompt in having the x ray examination made. If we do so we will save many lives.

In conclusion, let me emphasize that we will make correct diagnoses if we can only keep our attention fixed on the problem of trying to pick up these little deviations from the normal, getting the picture in our mind, being suspicious; picking up the little things by the wayside, and putting them together into a clinical picture; taking an x ray when our suspicions are aroused and the physical signs are equivocal or absent; and then, on the other hand, where we have physical signs and no constitutional symptoms, making sure that we are not dealing with an old lesion. These, it seems to me, are some of the high spots which are our problems in making health examinations as far as pulmonary tuberculosis is concerned.

379 Park Avenue.

The Prescription of Exercise and Diet*

C. WARD CRAMPTON, M.D.
New York

The most important part of the work of the health physician begins when he has finished his examination. With a thorough command of the subject of preclinical medicine, coupled with an ability to estimate its significance to the future progress of the health client, the physician should have little difficulty in arriving at a clear understanding of what the oncoming years will bring forth. The whole value of the examination depends upon the ability of the physician to modify the future life of his client favorably, to remove obstacles and dangers, and increase the margin of health, happiness and efficiency. This is of great importance to the client. It is of greater importance to civilization because the ripened service of valuable men is frequently rendered best in the decades after the age of fifty.

THE BASIS FOR THE PRESCRIPTION

Heredity.—In the client there is a tendency to develop those diseases and deficiencies which appeared in his family tree. He will deteriorate in a manner similar to its dead or dying branches. Your prescription should postpone a like fate.

Previous history.—Your client's previous history will show him damaged or vulnerable in definite ways. It is your duty to eradicate all the relics of the pathological past, and clean the tissues of danger and damage.

Habits of life.—The daily life of the health client, clearly recorded in all of its various phases in your history, contains the most important facts for your prescription. Men and women live mainly by instinct. They eat, work and sleep as their heredity and circumstances command. They do not direct their lives. They simply live, and into their lives creep a variety of maladjustments and habitual errors which daily repeated gradually cause deterioration and disease.

It is not enough merely to take a record of the habits of diet, exercise, rest, recreation and other economic and social factors. It is necessary to evaluate them and to apply this knowledge toward the correction and direction of the life of the patient.

Physical examination.—The results of the physical

*Read as part of a symposium on health examinations, presented under the auspices of the Medical Society of the County of New York and the New York Academy of Medicine, February 3, 1925.

examination of the client give further data for his instruction. You have analyzed his anatomical structure, observed his deficiencies and weaknesses and estimated their influence upon his future life. By various functional tests you have determined the efficiency of the internal organs. You have searched for signs of peculiarities in his constitution for the earliest preclinical foreshadowings of disease and you are prepared to take such measures as will prevent deterioration, forestall disease or cure it, if it is already present.

With this series of facts laid out before you, you are now prepared to give your prescription to your health client.

PARTS OF PRESCRIPTION FOR HEALTH CLIENT

In writing any prescription, we may well keep in mind the old instruction of our fathers in medicine: *"Curare, cito, tuto et jocunde"*—"To cure quickly, safely and pleasantly." All of these points are to be borne in mind in considering the various parts of the health client's instructions, which are:

More diagnosis.—The health examination is best conducted by the family physician in his own office in personal conference. It is true that a more extensive record may possibly be gained by putting your client through a battery of experts in different specialties, but this has the disadvantage of great expense, a loss of personal touch and a confusion of counsel. It is permissible only when the health client comes back to his family physician for interpretation, direction and comfort. The family physician is the ideal health consultant. He must, however, recognize the need for further diagnosis from laboratory or specialist. He can no more practise the health examination without frequently referring his cases for further diagnosis than he can practice all the specialties which they represent. The first part of the prescription, therefore, is often more diagnosis.

Drugs.—There will frequently be found in the health examination conditions which require recourse to the pharmacopœia. Drugs are indicated and should be given. The fact that this is a health examination must not exclude proper therapy.

Diet.—One of the greatest influences toward health or disease is the daily diet. This will be taken up in detail later in this article.

Exercise.—While exercise is one of the most important fields in the prescription of health, it can easily be overdone. Neither exercise nor diet should be considered curealls, nor should any physician be so far swayed in his recognition of their importance as to make an exclusive system of either.

Mode of living.—One of the most important parts of the health prescription is what I call "the twenty-four hour prescription." It is based upon the science of personal hygiene applied to the physical condition of the health client and all of the circumstances entering into his life. We seek to arrive at an optimum program that he can follow. It is absurd in most cases to prescribe the ideal, for the ideal prescription is one which is academic and not feasible. There must be considered the elements of work, worry, strain, hazards, habits, recreation, rest, outlook, and—what is most important but usually neglected—sex habits and familial and social relationships. The health consultant is placed in charge of the client's future life. Physicians are too frequently like the Pharisee, who passes by saying that these matters are unfortunate, but they do not concern him as a physician. The health consultant, on the contrary, must play the part of the good Samaritan, who steps out of his medical path to care for the whole man.

Encouragement.—The health consultant must not only lay out a feasible program but it must be made attractive enough to be followed. Men are not impelled to action by intelligence one tenth as powerfully as by emotion. The imagination must be stimulated. One hundred per cent. living must be made to seem worth while. A careful study must be made of human incentives and motives. Without these, the health prescription falls of its own weight and no good has been done.

Followup.—If the health client is not followed up, he soon tends to resume his previous pernicious program. A continuing health service must be rendered. This involves the following elements:

Further diagnosis from laboratory or specialist must be obtained if necessary, and the diagnosis completed. The health client should return at the end of thirty days to report his success in following his program. This tests the client and tests the program. The consultant then knows whether the impetus toward health has been sufficient and well directed, and he can renew it. Here it is important to have simple tests of health, which can be made by the client himself, as well as to supplement those which can be given in the physician's office. Every client should be given a health diary in which he records his progress toward one hundred per cent. health during each month, and, if necessary, any intercurrent illness. This must not be made the text of a sickness diary for the further involvement of neurasthenics. The client will return to the consultant's office upon call or at stated intervals, establishing a relationship which is wholly beneficial. Of course, it is important that the health client be given medical treatment if necessary.

The prescription.—In general, the prescription should be simple, clear, concise, definite, informative, complete and enjoyable. The consultant should prescribe nothing which, in similar case, he would not do himself, and the test of sincerity is whether or not he follows the instructions of his own health consultant. The form of the prescription is important. If it is given by word of mouth, it will fail. It should be written or printed. It should not be merely in the form of brief notes. The best prescription is in the form of a health booklet printed attractively, and containing, in addition to the prescription, a record of the important points in the examination, especially those in which the client can be expected to work for improvement, notably, the measurements of the chest, abdomen, posture, weight and strength. A record of pathology is, in general, best omitted. In this prescription, by the side of the client's record should be placed the standard he is expected to attain.

SUMMARY

In brief, the prescription should be based upon the complete study of the client. It should contain both medical and social elements; it should be stimulating, attractive and a permanent possession.

PRESCRIPTION OF DIET

There is a best diet for every man, woman and child. It is the purpose of the consultant to determine what it is and to get the client to follow it. The diet should be prescribed for the man and not for the disease. We are inclined to consider disease as an enemy which has gripped the patient. It is better regarded, however, as a physiological process, perhaps in some way gone wrong, but yet an endeavor on the part of the body to meet difficult and distressing conditions. We will then aid the physiological process rather than merely deliver a frontal attack on the disease. In general, we are convinced of the fact that a man's diet largely determines his health, happiness and efficiency. At the outset, diet will be regulated according to the age. The adolescent needs ample calories. The period of manhood is one in which the dietary sins lead to the disabilities of maturity. At the menopause these errors begin to show this, and in old age their maximum destruction is manifest.

GENERAL ERRORS COMMON TO CIVILIZATION

Excess of carbohydrates.—There is an average of 135 pounds of sugar taken annually by each man, woman and child in the United States. Cereals and starches are increasingly available. This is the result of an instinctive taste for this kind of food which is quickly transmuted into energy. Taken in excess, it is destructive. The reason why there is implanted in every modern child and man a desire for sweets is that in our previous uncivilized state, sugar was difficult to obtain, honey was hard to find and sugar cane was not generally cultivated. It required the implantation of a strong instinct to urge sufficient action to get it. We inherit the urge and have developed the supply far in excess of reasonable needs. The result is injury to the stomach, pancreas, colon, joints, arteries and capillaries, with fibrosis, obesity, diabetes, myocarditis and the like in its train. Sugar is best understood by this chemical definition—a hexatomic alcohol—and its excess should be regarded as preclinical to all degenerative diseases.

Excess of animal protein.—Meat, in our uncivilized state, was hard to get. It required a great deal of initiative and energy to bring home the wild game to the pot. Hence, the strong hereditary urge which makes a thick, rare beef steak the most satisfying article of food to the energetic middleaged man. An excess of animal protein is of greater toxicity than any other form of food. We not only eat too much of it, but enhance at one stroke its taste and destructive power in processes of preparation for the table. Too much animal protein is preclinical to every form of fibrosis and systematic deterioration.

Deficiency in vitamines.—With a desire to make food more palatable, cereals and other vegetables are robbed of their vitamines by cooking or refinement, with the result that civilized man, on a too well prepared diet, is suffering generally from vitamine starvation.

Deficiency in roughage.—The same process of cooking and refinement of food stuffs removes the elements of bulk and roughage which stimulate the digestive tract. Stagnation, with its train of resulting evils, creeps in, a variety of toxins are produced and work their results.

INDIVIDUAL DIETARY CONSIDERATIONS

Heredity.—The too frequently neglected prenatal history of the individual frequently gives an important clue to diet. We find in the ancestry many diseases which could have been prevented by proper diet. These, which are likely to appear in the client may be ameliorated, prevented or postponed by proper action. It should be remembered that every disease found in the ancestry is a preclinical sign.

Previous history.—Every disease from which the patient has suffered gives indication of one or more tendencies, or indicates a tendency for its own return in its own identity or in some disguised form.

Present habits.—Every client's history should include the following: a report on the customary menu for breakfast, dinner and supper; the particular foods which are especially liked or disliked; those which cause discomfort; the question of bowel movement; and the time and circumstances under which meals are eaten, there should be included an intestinal motility test by the use of carmine or charcoal.

Present complaints and physical examination.—The usual gastrointestinal symptoms should be considered and the constitutional elements which may be traced to errors in diet.

Additional considerations.—Age, race, religion, season, locality, income, intelligence and social status.

NATURE OF PRESCRIPTION

Omissions and limitations.—The most common limitations are, in the order of their importance, animal proteins, carbohydrates, salt, fat, water, bulk, with specific omissions based upon allergic sensitizations.

Prescriptions.—Varieties of food usually scanty or omitted from the diet should be emphasized. These commonly include bulk, vegetable proteins, water, milk, eggs, roughage, calcium and vitamine rich foods.

Element of intelligence.—It is often necessary to lay down a diet in detail, not simply stating what should be eaten and what should not be eaten. It is sometimes possible to give the client information on his condition and on the nature of the foodstuffs which he should use or discard. In the last analysis, the client is in charge of his own diet and he should have sufficient information on the subject to guide him intelligently. It is the consultant's task to arouse intelligent interest and bring it to bear on the problem.

Special diets.—Unquestionably, it will at times be necessary to advise special diets for pathological conditions. Complete or relative fasts, or the omission of a meal a day for various periods, now forms a recognized method in hygiene.

FORMS OF PRESCRIPTION

In the usual office call of a sick patient, unfortunately, the consideration of diet is frequently omitted. This mistake should not be made in the health examination.

Verbal prescription.—Instructions on diet given in cursory verbal form are most ineffective.

Written memorandum.—The written memorandum is fairly efficient. It unfortunately takes a great deal of time and is likely to be incomplete.

(To be concluded.)

Historical Medicine

Why the History of Medicine Should Be Studied by the Medical Profession*

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

One can never be fully in possession of a science until one knows the history of its development and this applies to medicine as well as to the philosophy of the sciences in general. It was not so very many years ago that the fevers existing along the coast of Greece were not understood and naval surgeons who met with them supposed that they were dealing with either a new form of typhoid fever or some new pernicious febrile affection. Then Littré confronted the modern descriptions with those found in the Hippocratic Collection, thus giving them their true names and real significance. Researches conducted in recent years have shown all this to be true and the diseases observed in the regions are the same as those described by Hippocrates more than twenty-three centuries ago.

Then, too, the very best procedures for reducing dislocations are found in the Hippocratic Collection and we know, according to the texts of Antyllus, that the operation for the cataract was extensively practised by the ancients, while in the Hindu text of Susruta there is found a very precise and detailed description of lithotomy.

The medical profession of today lives too exclusively in the contemplation of the socalled modern discoveries, and neglects—we will not say the work of the ancients—but that of our immediate predecessors. For example, the best editions of Laennec are now entirely out of print and the modern publisher, who well knows the requirements of today, would never dream of reprinting this classical work.

But the method in medicine has not changed; it is the same as that followed by Hippocrates and disdain of our predecessors, as Leibnitz has rightly said, will expose us to the same mistakes and the same uncertainties which in the past have delayed the progress of science. They may be better avoided when one takes advantage of the experience of the past: "to neglect the past of a science," says Dezeimeris, "means in reality that it must be recommenced every day." We agree that well observed cases will always retain their value and should be received with respect, yet on the other hand doctrines are changeable and require an incessant revision. There are periods in which their transformation takes place with such suddenness that it almost assumes the shape of a revolution and such great progress frequently leaves behind it a period of confusion which is propitious for marked reaction.

It is also quite true that an excessive and exclusive cult of medical history may lead to that state of inertia which caused the physicians of the sixteenth century, who only searched for the knowledge of truth in the Greek, Arabian and Roman authorities, to fall into contempt among all. This state of affairs, however, could only be due to abuse, and the abuse of erudition in medicine certainly need not be feared at the present time.

In examining the history of medicine the question of the history of disease or historical pathology must not be overlooked. It is a vast field and certainly represents the most important part of the history of the healing art. Historical pathology gives us descriptions of disease in all ages that could be exactly applied to the diseases of today, thus showing that there are diseases of all time and all places. These maladies form the common property of human pathology; they are the inevitable result of the conflict of man with his surroundings and his struggle with the general forces of Nature. Without speaking of those traumata to which man has been exposed in all places and for all time, one meets with morbid processes arising from the influence of heat, cold, dryness and dampness. Here again we will find those morbid processes which will afflict man to eternity, the cause of which is the result of passions, excesses of all kinds and neglect of hygiene. Medical history also shows us other diseases which, although not occurring in all places, have existed in all times, and reciprocally. For example, may be mentioned diseases of the seasons of the year, febrile affections of a continuous type and those having an intermittent or pseudocontinuous type, affections produced by poverty, those which arise during great social revolutions and those resulting from intoxication from food and drink.

Historical pathology also shows that the diseases unceasingly increase and, although this may appear a paradoxical coincidence, it is true that they do increase in spite of the great progress in hygiene as we advance through the ages. However, the majority of these diseases which successively appear in medical history are not new diseases; they are diseases which, with the progress of science, have been recognized as types apart. Thus diseases of the heart have come to the front through the progress of diagnostic methods, likewise diseases of the kidney, and then suddenly a given renal affection will be separated from the common group. All this applies to diseases of the brain and cord. And here history notes in this great progress the names of Corrigan, Bright, Rostan and Duchenne.

On the other hand, historical pathology shows us that some of the diseases described by the ancients have disappeared, while others have been simply dormant for centuries and suddenly reappear from time to time; others appear to be definitely extinct, and nothing leads us to suppose that they will reappear.

Historical pathology is followed by the history of nosography. First, symptomatology was developed and perfected. After having studied disease from external signs, on the surface so to speak, the time

*The Introductory Lecture to the Elementary Course on the History of Medicine at the University of Geneva, delivered April 25, 1925.

finally came when each organ was individually examined and perfected diagnostic methods have resulted in the perfecting of instruments for physical examination.

The prognosis and etiology of disease were the great glory of the ancient physicians, and it is not too much to say that little has been added in modern times. Yet modern medicine has marvellously perfected symptomatology and diagnosis, but in so doing it has only verified the truth of ancient acquisitions made in the domain of etiology and the prognosis of disease. On the other hand, pathological anatomy is a modern science founded by the great Italian physician, Morgagni, although all justice must be done to Theophilus Bonet, of Geneva, who wrote his *"Sepulchretum, sive Anatomia pratica ex cadaveribus morbo denatis," Geneva, 1679,* which formed the foundation stone for the work of the physician of Bologna. By the more complete knowledge of lesions accompanying disease and specifically characterizing it, pathological anatomy has tardily given us a more exact idea of the morbid species. Yet history shows us that physicians were not entirely without the information necessary to form a conception of the nature of morbid processes.

Therapeutics at the beginning had gone far beyond the other branches of medical science, and in truth they even preceded the observation of disease. The innate sentiment which forces man to alleviate pain in others made him search from the earliest times the means of cure, but at the beginning he invoked the clemency of the higher powers and asked assistance from his familiar deities. Prayers, sacrifices and incantations were the first attempts at therapeutics. These practices are found today among all primitive people and those whose civilization has decayed.

Inversely from what is done today, man at a later period did not search for general indications for treatment, but he asked of others who had had experience what plant was successful in controlling a given symptom; there was no method in therapeutics, there were only remedies. But the number of these increased daily and to plants were added the use of metals, which in the Islamic school acquired a very great importance. It was not always a successful empirical trial which introduced a new drug into therapeutics; it was more often some futile consideration deducted from mythological attributes or gross analogy. Hygiene, which is derived from physiology and etiology, is contemporary with the study of the cause of disease, or perhaps it were better to say that it was born from the terror of rather than the knowledge of disease. It had been an art before it became a science. In Egypt and in all the Orient hygiene was a part of the religious cult and the sacerdotal injunctions imposed upon the people introduced into their customs many practices which are today applied in a modern form. With the Greeks hygiene became a science and has progressed from their day on.

The amount of knowledge accumulated in the past is enormous, no matter what may be said to the contrary, and historical nosography shows that it has bequeathed a large part of its treasure to modern medicine, because all that which is based upon observation is imperishable. But the ancients were not content merely to observe; they wished to rise to a conception of the nature of disease, yet they could not resist the temptation prematurely to systematize. The history of medical doctrines is that part of the history of medicine which shows the greatest fragility, fluctuations and successions of the various systems. Although the facts have remained unshaken, all the older theories have crumbled away. This could not have been otherwise, because the essential foundation, namely physiology, did not exist, and the physical sciences were in their infancy. One can appreciate impartially these ambitious efforts only if he places himself in the intellectual environment of the time; so the study of the history of medical doctrine can only be carried on by keeping account of the relationship of medicine with all the sciences.

Today the science of man in the normal state forms the basis of pathological research, but anatomy and physiology were only acquired late in the development of the healing art. This, of course, is natural, because in the early days the first requisite of the physician was to relieve suffering and to fight against death. At a later period he had more leisure to devote to study and pathology should have been his first preoccupation, and he was not long in discovering that it was vain to discourse upon the disturbances of an organism, of whose structure he was ignorant; and the desire seized him to know what was beneath the skin, what was suffering and what had become diseased. Besides being, as it is to us today, the end of natural existence, death had a solemn and mysterious character; religious terrors protected the remains of man who had lived; therefore the dissection of human bodies exposed the physician to punishment by death down to the middle ages and even later; dissection was a foolhardy act in days when capital punishment was applied to generals who had left the bodies of their soldiers unburied.

Yet the physician could not be content with the anatomical data derived from the executioner or priest; the induction derived from the examination of animals' entrails were insufficient to satisfy the minds of learned men. It is, however, doubtful whether or not the first anatomists had any other means to information; neither Aristotle nor Hippocrates had ever opened a human body, and the teaching of human anatomy was first carried on at the School of Alexandria by Erasistratus and Herophilos.

As has already been said, physiology could only be developed at a late date and necessarily is far more recent than anatomy as a science. Unquestionably it had a beginning in the distant past but it did not form a body until modern times; Harvey and Lavoisier are the two great names which mark the beginning of its vigorous growth. Therefore for many centuries medicine was deprived of this important branch, but it must not be supposed that physicians resisted the invincible temptation to explain the phenomena of life. But in the absence of a positive physiology they created an imaginary, which was modified according to need and to the trend of the philosophy of the times.

We may therefore conclude that the utility of medical history resides in the fact, as Littré pointed out a century ago, that "there is nothing in the most advanced contemporary medicine whose embryo cannot be found in the medicine of the past," and this statement is as true today as when the great French medical historian uttered it.

Teeth in Olden Times*

THE HONORABLE WILLIAM RENWICK RIDDELL, LL.D.
Toronto, Canada

(*Continued from page* 549)

But before this there was much progress from the earlier practice. Filling with lead (plombage) and artificial teeth were not uncommon—it is said that Henry IV, Henry of Navarre, paid twenty sous a month for dentists' care of his teeth, and there is an account still extant for "gold to fill (plomber) the King's teeth" (27). But gold was not often used: Ambrose Paré recommends cork and lead, and the use of lead was so common as to give rise to the word *plombage* for filling generally. Prosthesis, too, had reappeared in the sixteenth century.

Paré advises: "When they fall out, others should be fitted in, of bone or ivory or shark's teeth which are excellent for that purpose and which are to be tied to other neighboring teeth with gold or silver thread" (28).

Nor were full sets of artificial teeth unknown: they were not extremely useful, indeed, being rather for show than for mastication. One Court lady, we are told, had a set of teeth of the seawolf (*loup marin, Labrax lupus*)—"She removed them when eating but she replaced them to speak more easily and that cleverly enough. At the table when others were talking, she removed her set of teeth and hurried to eat; then she replaced her set to unload her budget" (29). A satirical writer informs us in 1605 that "many . . . had artificial teeth which they removed before seating themselves at the table" (30). It would appear that the manufacture of false teeth was in the hands of the turners (tabletiers). Some of the practitioners claimed more success in their work. We are told of Catalan of the Rue Dauphine, who "Will make you a complete set with which you will masticate all foods without discomfort and without effort"—this was late in the eighteenth century. At that time it is said that ivory, human teeth, teeth of cattle and walrus were almost exclusively employed: and one practitioner advertised (in 1786) that he had discovered springs made of gold to hold as firmly as possible the artificial sets of teeth for mastication and talking. "These sets of teeth are shaped to imitate nature and to make all the movements of the mouth without being liable to break—they serve, especially in the absence of natural teeth, for trituration of the food—that, as is well known is the foundation of the whole animal economy" (31). Even those in high station did not always have sets of teeth—Madame de Maintenon in 1714 writes: "I can scarcely see, I hear still worse and I am no longer understood because pronunciation is gone with the teeth" (32).

The transplantation of teeth, the immediate replacement of a carious tooth by a sound human tooth, although doubted by Ambrose Paré, is said to have been successfully practised thirty years later, in 1615, by Dr. Louis Guyon—this, however, was again a century later doubted by Dionis (33).

Let us now leave this field and see what were the officinal medicines: for that end, we are not driven to conjecture, gossip or tradition.

Moses Charas in 1673 published at Paris his *Pharmacopœia.* In 1753 Louis-Guillaume Lemonnier, afterwards one of the Royal Physicians of Louis Quatorze, Louis Quinze and Louis Seize published at Lyons an improved edition in Latin and French which was translated into all the languages of Europe and even into Chinese. This is a perfect mine of lore pharmaceutical and is undoubtedly reliable (34).

I gather from this *Pharmacopée Royale* some flowers of dental significance.

For toothache, Agaric Troches are recommended: take two drachms of white ginger contused, four ounces of white wine, half a pound of choice agaric in powder—make troches according to the rules of the art (35). This was a wondrous medicine, good for stomach, kidneys, liver, spleen and uterus; it cured headache, pains in the eyes, ears and teeth—besides killing worms.

Cynoglossus pills were very efficacious: take six drachms of choice myrrh, five drachms of the root of olibanum, half an ounce of each of dry cynoglossus root, seed of white hyoscyamus, and extract of opium, and an ounce and a half of each of saffron, castoreum and gum styrax (36). These are much esteemed for fluxions from eyes, teeth, etc.; and to facilitate slumber by allaying pains.

But the real thing for toothache is the Oil of St. John's wort, *Oleum hyperici*—take two pounds of the top flowering leaves of St. John's wort approaching maturity, bruised, four pounds of olive oil, half a pound of generous wine, two pounds of Venice turpentine, three ounces of tincture of saffron (37). This makes a balsam for pains in the joints, for sciatica, gout and even for toothache. That it heals all kinds of wounds (even those of the nerves), burns, etc., of course follows: but then "it is good also for worms and convulsions" when applied externally.

Then there were the *Pilulae sine Quibus,* pills without which one should never be found. Take fourteen ounces of the extract of Socotrine aloes, prepared with the juice of white roses, six drachms of diacridium, half an ounce of each of the whitest agaric, choice rhubarb and cleaned senna leaves, a drachm of each of red roses without the stem, the tops of absinth, seed of violets, dodder and mastic. Make pills (38). These pills are splendid purgatives and "are strongly recommended in diseases of the head and particularly in those of the ears and eyes they are taken fasting after the first sleep or in the morning."

Dentifrices were not unknown. Apparently there was not the variety we now enjoy, in fact I find only three, being Pulvis Dentifricus, Nos. 1, 2 and 3 respectively.

For Pulvis Dentifricus, No. 1, take one ounce of each of root of Florence iris (i. e., orris root), pumice stone and stag's horn calcined, prepared red

*Read before the Academy of Dentistry, Toronto.

coral, sepia bones, and cream of tartar, all very finely pulverized; half a scruple of each of oriental musk and civet and two drops of each of distilled oils of rosewood, cloves and cinnamon—this may be mixed in a marble mortar with equal parts of syrup of mulberries and kermes to make a paste (39).

The author says, "I know that there is no want of powders or pastes for cleaning and whitening the teeth; but I can assure you that this recipe is very good whether it be used in powder or in paste; for in addition to cleaning and whitening the teeth, it also prevents decay and stabilizes them."

Pulvis Dentifricus, No. 2, is simple: Take two ounces each of tears of dragon's blood and burnt common alum, finely pulverized; and four grains of oriental musk—this may also be made into a paste with the same syrup. "The use of this composition whether in powder or in paste is to rub the teeth gently evening and morning or even every hour if desired" (40).

For Pulvis Dentifricus, No. 3, take half an ounce of each of calcined pumice stone, white coral, sepia bone and cream of tartar all prepared on a porphyry slab, and orris root finely pulverized; one drachm of sal ammoniac similarly pulverized, three grains of each of oriental musk, and ambergris (41), "this powder is also very good for cleaning and whitening the teeth. It is used either in the state of powder or better, mixed with syrup of coral or dry roses or rose-honey and then it is made into a paste before scrubbing the teeth." This rose honey, Mel rosatum, made of dried red roseleaves and very white honey, was used by itself to clean and whiten the teeth. We may close our account of this work by extracting the formula for a balsam to promote the growth of the teeth in children; it is called the Balsamum ad puerorum dentitionem but there is no restriction of its use to *pueri,* boys; and no doubt it was equally beneficial to the dentition *puellarum,* of girls.

Take three ounces of unsalted May butter, two drachms of each of hen and duck fat; two ounces of each of the juice of river crabs, contused, extracted by cornflower water, also of mucilage of marsh mallow; four ounces of pulverized sugar candy; the yolk of an egg, and six grains of musk and of ambergris, mix and make a balsam (35). You crush two or three live river crabs in a marble mortar with a wooden pestle, moisten them with a little cornflower water and then press out two ounces of fluid; prepare two ounces of the mucilage of marsh mallow root, put the whole into a vessel of glazed earth with three ounces of May butter, two drachms of chicken fat and as much duck fat, cover the vessel and heat at a slow fire till the fluid almost disappears; then strain through linen, add (without fire) the yolk of an egg with the sugar candy, the musk and the ambergris finely powdered and the balsam is made (42).

It is a tried and approved preparation "for softening the gums of small children when their teeth are ready to come out; and the nurse should take care to anoint them with it often. Its use is very handy for, not being disagreeable to the children, it cannot hurt them if they swallow it."

Leave we the Old World and come to the New.

Nicholas Monardes, a Spanish physician, was born at Seville in 1493, the year after Columbus discovered America or at least Islands off America: Monardes did not visit America but he investigated the medicinal properties of American plants and other materials introduced from the New World. He published a book at Seville in Spanish, 1565, with the title *Dos Libros de las cosas que se traen de las Indias Occidentales que Serven al uso me Medecina,* (Two Volumes Concerning Things Brought from the West Indies Which are Used in Medicine). This work (after being reprinted in 1569 and 1580 a third volume being added in the last edition) was translated into Latin by Charles Clusius or L'Ecluse, and published in one volume at Antwerp in 1574—this is the edition which I use (43).

I give the plants only which were used for the teeth; most of them had great efficacy also in the case of disease of the other parts.

The marvellous Tacamahaca from New Spain in addition to its other virtues, "allays toothache when applied to the teeth even if they are decayed: and if the decayed tooth be burned (cauterized) it will prevent further decay" (44).

The Caraña brought from the interior of the Continent by way of Cartagena and Nomen Dei cures everything that the Tacamahaca can cure and more quickly (45).

Then there was tobacco which a few years before that time, indeed, had been brought to Spain, "rather for the ornamentation of gardens, than because of its qualities; but now it is very much more noted for its qualities than its beauty." It would be impossible to enumerate all its wondrous medicinal virtues, but the enthusiastic author can say: "Not only does it terminate pain of the teeth arising from a frigid cause the tooth having first been rubbed with a piece of cloth soaked in its juice and a little pill made from its leaf having been inserted in it; but it also checks decay so that it creeps no further" (46).

The fruit and other parts of a tree not named but described as being of the size of the ilex or scarlet oak with bark like that of the Cerrus Aeglyops or Turkey oak and leaves like the ash are much praised. "The teeth are stabilized by the powder rubbed on them and receding gums are healed" (47).

"Three years ago there was brought from Mechoacan province a certain root called *carlo sancto,* whose distinguished qualities they preach."

"This same plant when chewed helps receding gums and stabilizes the teeth: it also frees them from roughness and decay, and improves the breath: but after use, the mouth is to be washed out with wine to take away the bitter taste" (48).

"A few days ago the Bishop of Cartagena brought from the mainland of the New World the fruit of a tree from which dropped that tear which they call dragon's blood."

Among other qualities "it reunites recent wounds, it frees the gums from putrefaction and stabilizes the teeth" (49).

We can appreciate the great esteem in which the inhabitants of the Province of Quito held the teeth when we learn that "the inhabitants of this region are called guancanilcas and are toothless, for they have a custom to draw their teeth which they offer up to their idols, saying that the best should be offered to them and nothing is more distinguished for a man, nothing more necessary, than the teeth" (50).

Petrus de Osma et Xarayzeio writing to Monardes

from Lima, December 26, 1568, expresses the fear that the Indians had sacrificed to their idols a boy of their race because he had disclosed to the Spaniards where to find Bezoar (51) stones for "the Indians hold these stones as very valuable and offer them at the shrines of their idols which they call Guacas and they are accustomed to offer up other very valuable things such as gold, silver, gems, necklaces, animals and boys" (52).

Perhaps the modern dentist has now heard enough of these old time teeth: but I cannot refrain from adding something of the wonderful qualities of guayacan—our guaiacum.

Its use in the treatment of the *morbus gallicus* is well known: but its other virtues seem to have been obscured by time—anyway, Monardes tells us that "it stabilizes the teeth and whitens them if they are quite frequently washed with it," i. e., with the infusion or tincture (53).

NOTES

1. *Outlines of the History of Medicine.* . . . by Joh. Hermann Bass, M.D., Dr. Handerson's edition, N. Y., 1889, p. 15.

2. *odous,* genitive *odontos,* is, of course, Greek for a tooth. The compound of *odous* with references fill three folio columns of Stephanus' ponderous *Thesaurus,* vol. iii, coll. 3481 B-3484A.

3. Cicero, *De Naturâ Deorum,* Lib. iii, c. 22, enumerates three Aesculapii; the first was the son of Apollo and Coronis, "the bearded son of a beardless father" as the Greek wags called him; he discovered the *specillum,* the sound or probe for examining the depth of wounds, ulcers, &c., and was the first to bandage wounds. This is the God of Medicine. The second Aesculapius was struck by lightning and lies buried in Arcadia—the third, the son of Arsippus and Arsinoe *qui primus purgationem alvi, dentisque evulsionem, ut ferunt, invenit*"—"who was the first, so they say, to discover purging and tooth extraction." Cicero knew as much about such things as anybody—and that was not much.

4. After centuries of orgies of tooth pulling, and the sacrifice of millions of good serviceable teeth we are about back to the Greek idea. Dr. Box will save millions more—more power to his elbow!

5. We owe to Cælius Aurelianus (a celebrated Latin physician concerning whose period there is much uncertainty some placing him in the 1st century, A.D., and some as late as the 5th) the information that the lead forceps came from Erasistratus. See Cælius Aurelianus, *De Morbis Chronicis,* Haller's Edition, Lausan, 1774, Vol. ii, p. 135—the passage is part of Aurelianus' *Chronicles,* lib. ii, c. 4. The passage is given verbatim in Du Cange's *Glossarium Mediae et Infimae. Latinitatis,* Vol. ij, p .802, *sub voc Dentiducum*—I extract the substance: *"plumbum odontagogum . . . apud Delphos in Apollinis templo ostenationis causa propositum quo demonstrature oportere eos dentes auferri, qui sint faciles, vel-mobilitate laxati, vel quibus sufficiat plumbei ferramenti conamen ad summum."*

The dentiducum for drawing teeth was also called *forfex dentaria* or in late Latin *dentaria—"ferrum unde Medici dentes tollunt."*

Erasistratus of Iulis in Cos lived in the 3rd and 4th centuries, B.C., in Antioch and Alexandria. His most famous medical feat was the diagnosing of the puzzling illness of Antiochus, son of King Seleucus Nicator, as being love for Stratonice his stepmother: he got a fee of one hundred talents (say one hundred thousand dollars). He rejected Hippocrates, discarded bleeding and purgation and was the prototype of Hahnemann in his theory of the powerful effects of the smallest doses of medicine: he invented a catheter and just missed discovering the circulation of the blood—had it not been for the old theory of *pneuma* he probably would have done so.

6. See Hippocrates, *Peri Pathon:* De affectionibus, Sec. 4. It should be said, however that there is much doubt whether Hippocrates really wrote this book—it will be found in Kuhn's useful edition, vol. ii, p. 380, Littré's splendid edition has this in vol. vi, p. 213. I find in Hippocrates' celebrated *Aphorisms* only three references to the teeth, I translate.

Aph., iij, 25.

At the time of dentition there is pruritus of the gums, fevers, convulsions, diarrhea and particularly when they are producing canine teeth. . . .

Aph., v, 18.

Cold is harmful to the bones, teeth, nerves, cerebrum, spinal marrow; heat is beneficial.

Aph., iv, 53.

Fevers become more acute in those around whose teeth viscous matter forms.

7. *Cum sis ipsa domi, mediaque ornere Suburra*
Fiant absentes et tibi, Galla, comae;
Nec dentes aliter quam Serica, nocte reponas
Et jaceas centum condita pyxidibus
Nec tecum facies tua dormiat; innuis illo
Quod tibi prolatum est mane, supercilio
. . . . . .

Martial, Epig, ix, 38.

"When you are at home, doctor yourself up with paint and powder, leave off the wig, too—lay aside at night your teeth no other wise than your silk garment and throw a hundred secret things in their boxes—and don't let your own face sleep with you—beckon with that eyebrow which is brought to you in the morning" (out of the box). The rest of this scurrilous Epigram, I do not copy even in the decent obscurity of a learned language—it is too vile for even the Delphin editors to paraphrase. The lady did not wear silk pyjamas—she, like all others till a few generations ago, lay "in naked bed."

Who Galla was does not appear: and the commentators do not help us—she seems to have been just "that d—— Frenchwoman."

8. *Nostris versibus esse te Poetam,*
Fidentine, putas, cupisque credi?
Sic dentata sibi videtur Aegle
Emtis ossibus, Indicoque cornu:
Sic, quae nigrior est cadente moro
Cerussata sibi placet Lycoris.
Hac et tu ratione, quâ Poeta es,
Calvus cum fueris, eris comatus.

Martial, Epig., lib. j, 73.

These Fidentinus, Aegle and Lycoris are all unknown to fame.

9. So says Cicero (or whoever was the author of *De Legibus*) lib. ij, c. 24.

10. *Auro cum iis qui bene haerent vinviendi sunt*—"they are to be tied with gold to those which are holding fast." Celsus, *De Medicina,* lib. vij, c. 12 (1).

11. See as to Celsus, Bass, *op, cit.,* pp. 161, 162; he was the father of mediaeval medicine. Apparently the Hindus and Egyptians long before this time "attempted to replace lost teeth by attaching wood or ivory substitutes to an adjacent sound tooth by means of threads or wires; but the gold fillings reputed to have been found in the teeth of Egyptian mummies have . . . been shown to be superficial applications of gold leaf for ornamental purposes." *Encyclopedia Britannica,* 11th Ed. *sub voc.* Dentistry. Our colored brethren and sisters still have a fondness for gold teeth—a failing not wholly unknown in the white races.

12. Much of the information in this part of the paper is derived mediately or immediately from Alfred Franklin's entertaining series *La Vie Privée d'Autrefois*—Paris, 1894. There is no pretence here of originality, and I trust that this general acknowledgment may make it unnecessary to specialize. I have verified quotations and statements wherever possible. The "gargarisme" is given in *Le Menagier de Paris,* Paris. 1393, vol. ij, p. 25.

13. The Royal Dentist was Guillaume Coureil: Francis died of syphilis—but that is a matter of detail.

14. Within half a century I have known in Ontario a family of French Canadian origin use the same dentifrice: and I am assured by one who should know that this custom still prevails among the peasants of Normandy.

15. Laurent Houbert (1529-1583) was Chancellor of the famous medical school of Montpellier. It is said that of his work *Erreurs populaires au fait de la Médecine et Régime de Santé,"* 6000 copies were sold in six months: his most revolutionary doctrine was that a foul smell was not conclusive evidence of putridity. He did not—as he might—cite our skunk!

16. See Brantôme's *Oeuvres.* (1740), Vol. viii, p. 13. Pierre de Brantôme (1540-1614) is a celebrated French chronicler.

17. A letter from Gui Patia to his friend and pupil Noël Falconet, June 19, 1661. Gui Patin (1601-1672) a French physician (and also wit and free thinker) a friend and pupil of Riolanus, graduated M.D. in Paris, 1627, and practised in that city all his professional life, becoming Dean of the Faculty and Professor of Medicine. He was a determined enemy of antimony and chemical medicine generally. He was the first to note a case of tubal pregnancy, which he attributed to a straying of the ovum. A great scholar and humanitarian, his chief consolation on his death bed was that he would meet in the other world, Aristotle, Plato, Vergil, Cicero and his beloved Galen.

Noël Falconer (1644-1734) of Lyons was a pupil of Patin's but was of the opposite school, an Iatrochemist and a thoroughgoing follower of Sylvius.

18. So says the surgeon, B. Martin, in his *Dissertation sur les Dents,* Paris, 1679, p. 64.

19. N. de Blégny; *Le livre commode pour 1692,* vol i, p. 172, vol. ii, p. 178.

20. J. B. Thiers; *Traité des superstitions,* Paris, 1697, vol. i, p. 375.

21. Dr. Th. Sonnet de Courval; *Satyre contre les charlatans et pseudomédecins empyrigues,* 1610; see pp. 107, sqq.

22. *Les secrets du Seigneur Alexis:* Paris 1691, p. 351. Seigneur Alexis was Girolamo Ruscelli, who died 1566.

23. Madame Fouquet; *Recueil de remèdes faciles et domestiques,* 1678, p. 73.

It may be of interest to note here that Dubois, the exodontist charged with drawing the teeth of Louis Quatorze, used for that purpose an *elevatoire* of new invention. We are not told of what material that instrument was made though Dionis praises it almost fulsomely. But Dionis does say of the instruments used for cleaning the teeth that while such instruments are usually of steel, those made use of for the King and the Princes are of gold—"and if there had been a still more precious metal it would have been used for them, because they pay magnificently." Let all dentists, and especially "scalers", take notice!

Dionis, *Cours d' Operations de Chirurgie,* Paris, edit., 1714, pp. 512, 519.

Charles-Arnault Forgeron, dentist of King Louis Quatorze with the title "Surgeon-Operator for the Teeth," had an annual salary of 2295 livres (about equivalent to seven thousand dollars at the present time); he filled the same office for the Dauphin and Dauphiness receiving one thousand five hundred livres (say five thousand five hundred dollars of present time value). His duty was to clean and cut the teeth and to furnish roots and opiates when the King washed out his mouth. Trabouillet, *Etat de la France pour 1712,* vol. i, p. 178. The King had an opening in his upper jaw through which every time he drank or gargled carried the water into his nose: the hole was made by a shattering of the jaw drawn with the teeth—it became carious and sometimes ran caries with an evil odor. Dubois used no other remedy than the actual cautery with a red hot iron and effected a radical cure. *Journal de la Santé de Louis XIV,* pp. 162, 164, 294.

(The word which I translate "shattering" is *eclatement;* it is now obsolete and seems to have been used generally of outcry, &c.). Louis Quatorze had bad teeth anyway: from 1685, thirty years before his death, he had hardly any in the upper jaw and those in the lower jaw were carious—when he had toothache, d'Aquin, his physician, used essence of cloves and of thyme; when an abscess formed, a cataplasm of bread crumbs was applied; if an operation seemed necessary, the surgeon and dentist were consulted and the dentist operated. Op. cit., pp. 135, 140, 160.

24. Peter Dionis, born in Paris, was lecturer in surgery and anatomy in the Royal Gardens at Paris, an office founded by Louis Quatorze, which position he held till his death in 1718.

The work referred to in the text is his *Cours d'operations de Chirurgie demontrée, au jardin Royal de Paris, Paris,* 1707, which has been frequently reprinted and translated into nearly all the modern languages. He wrote a monograph on *Epilepsy,* was the first to emphasize the effects of rickets in the pelvis and had some part in advancing scientific dentistry. See p. 521.

25. Including one for syphilis described as "a radical cure for all the most characteristic of the secret diseases without keeping bed or room, by Sieur Grand-Thomas, formerly surgeon in the Royal Hospital, tried under the eyes of Messrs. Fermelhuys and Lemery, doctors-regent in Medicine of the Faculty of Paris, without frication or salivation."

26. Louis, Dauphin of France, who married Marie Joseph of Saxony and by her became the father of the future Louis Seize: he died in the lifetime of his father and never became King.

27. The price was fifteen liv. fifteen sols, intrinsically about three dollars, equivalent to sixty dollars now.

28. Ambrose Paré, born 1509 or 1510, died 1590, originally a barber, was in reality the father of modern surgery; he substituted ligature for boiling oil to close the arteries in amputations, and contended for the uselessness medicinally of mummy and unicorn's horn—he performed herniotomy for strangulated hernia and reprobated the practice of emasculation as a radical cure for hernia, was the first since ancient times to employ the truss habitually, he recognized fracture of the neck of the femur and induration of the prostate, &c., &c.,—in short, it is not too much to say that he revolutionized surgery. He was Royal Physician to Henry II, Francis II, and Charles IX, the story of his having been protected by the last named by being hidden under the Royal bed on the night of the St. Bartholomew Massacre is probably untrue, as he was a Roman Catholic. The references are to his *Oeuvres,* 1573, pp. 612, 805.

29. Talleyrand des Reaux, *Historiettes,* vol. ii, p. 346, tells us this of Mlle. de Gournay, *"la fille d'alliance"* of Montaigne—the last sentence contains a delightful pun. *Râtelier* means either a rack or a "set of teeth"—*râtalée* means a rakeful; the lady is said to have replaced her râtelier to speak her râtelée—elle remettoit son râtelier pour dire sa râtelée."

30. Artus d' Embry in his satirical work, *Description de l'Isle des Hermaphrodites,* Paris, 1605, p. 105.

31. See Alf. Franklin. *La Vie, Privée d'Autrefois, Variéties Chirurgicales,* pp. 171, 172,, *Affiches, Annonces et Avis Divers,* December 29, 1780, p. 201.

32. A. Geoffroy, *Madame de Maintenon d'apres sa Correspondance,* vol. ij, p. 352.

33. Ambrose Paré, *Oeuvres,* p. 611. "That I have heard told, but I have not seen it: and if it is true, it may well be" —which sounds like a truism.

Louis Guyon, *Le Mirour de la Beauté et Santé Corporelles",* Paris, 1615, p. 369.

Dionis, *Cours d'Operations de Chirurgie,* 1714, p. 523.

Those authors are however speaking more particularly of the immediate replacement in the alveolus of a tooth drawn in mistake for another.

34. Moïse (Moyse or Moses) Charas was born in Languedoc in 1618 and followed his profession as apothecary at Orange and later at Paris. Being a Calvinist, he was forced to leave France in 1680—he went to England, then to Holland, then to Spain to attend Charles II. Disputing the contention of the Court physicians (firmly believed in by the Spanish people of the district) that the vipers for twelve miles around Toledo were harmless ever since they had been deprived of their poison by the fiat of a famous Archbishop, he fell into the hands of the inquisition, whence he escaped only by abjuring his Protestantism. He returned to Paris, 1690, where he lived until his death in 1698.

Monnier or Le Monnier or more correctly Lemonnier is known only by this work—he modestly hides his identity under initials describing himself on the title page as "M.L.M. de l'academie Royale des Sciences et Docteur en Mèdecine de la Faculté de Paris." The work was published *"avec approbation et privilege du roi,"* the license being dated seven years before publication, July 16, 1746. He was not yet Royal Physician. See Alfred Franklin's *La Vie Privée, Les Médecins,* p. 169.

35. ℞ *Zingiberis albi contusi, drachm, ij, Vini albii unc. iv. Agarici electi in pulverem redacti, libr. s. Fiant ex arte trochisci,* p. 277.

36. ℞ *Myrrhae electae drachm, vj, Olibani, drachm v. Radicis cynoglossi siccae, seminis hyoscyami albi, extracti opii, ana, unc. s. Croci, castorei, resinæ stiracis, ana drachm. js.*

37. ℞ *Summitatum hyperici floridarum, ad maturitatem vergentium, contusarum, libr. ij. Olei communis, libr. iv. Vini generosi, libr. s. Terebinthinæ Venatae libr. ij. Croci tincturae, unc. iij.* Venetian Turpentine was not a turpentine but a compound of many drugs.

38. ℞ *Extracti aloes soccotrinae cum succo rosarum pallidarum parati. unc. xiv. Diacridii, drachm. vj. Agarici albissimi, rhabarbari electi, foliorum senae mundatoryn, ana unc. s. Rosarum rubarum exungulatarum, summitatum absinthii, seminis violarum, cuscutae, mastiches, ana, drachm j. Fiant pilulae.*

39. ℞ *Radicis ireos Florentinæ, lapidis pumicis et cornu cervi ustorum, coralli rubri praeparati, ossis interioris sepiae et cremoris tartari, tenuissime pulveratorum, ana, unc. j. Moschi orientalis zibethi, ana, scrup. s. oleorum ligni rhodii, caryophyllorum et cinnamomi, ana, gutt. ij.*

The root of the Florentine iris is our orris root; Zibethum orientale is from the civet and is so called to distinguish it from *sibethum occidentale, i. e. stercus humanum,* from the superior animal. Kermes is the dried body of the female of a species of insect not unlike the cochineal, which grows on several species of oak in the basin of the Mediterranean; they were long thought to be berries. What the French call *Kermes du nord* or *Kermes de racines* are red berries. And there is a Kermes mineral; but the insect is here meant. The rosewood here named is not our rosewood, but the odorous wood of two species of Convolvulus, native to the Canary Isles; the famous English herbalist Culpepper recommends it to "encrease milk in nurses."

40. ℞ *Lachrymarum elegantium sanguinis draconis et aluminis romani usti, subtilissime pulveratorum, ana, unc. ij. Moschi orientalis, gran. lv.*

41. ℞ *Lapidis pumicis usti, corodli alni, ossis sepia et cremoris tartari, supra porphyrium praeparatorum et radicis ireos Florentinae subtilissime pulveratae, ana, unc. s. Salis ammoniaci similter pulverati, drachm. j. Moschi orientalis et ambrae grisae, ana, gran, iij.* The "porphyry" or "porphyvium" was a porphyry slab used by apothecaries for pulverizing and mixing their drugs.

42. ℞ *Butyri mayalis non saliti, unc. iij. Pinguedinis gallinae et anatis, ana, drach, ij. Succi cancrorum fluviatilium contuso um cum aqua florum cyani extracti et mucilaginis radicis altheae, ana unc. ij. Sacchari candi subtiliter pulverati, unc. iv, Vitellum unum ovi. Moschi et ambrae griseae, ana, gran. vj. M. f. balsamum.*

The *cyanus* whose flowers are used is the *Centaurea cyanus,* the common blue cornflower sometimes called the bachelor's button, blue bonnet or blue bottle; it grows very commonly in wheat and is often cultivated.

43. I owe to the kindness of Dr. J. H. Elliott of Toronto, the opportunity of examining this edition. The title is *De Simplicibus Medicamentis ex Occidentali India delatis. quorum in Medicina usus est.* Auctore D. Nicolo *Monardis Hispalensi Medico, Interprete* Carolo *clusio, Atrebate / Antverpiae. Ex Officina Christophoro Plantim,* Architypographi Regii, M.D. LXXIII.

The work was reprinted in Spanish in 1578 at Burgos, in Italian in 1585 at Venice, in Latin in 1579 and in French at Lyons in 1602 and 1629, the French being a translation of the Latin by Anthoine Colin, an apothecary of Lyons.

Monardes was a physician practising in his native city of Seville; he wrote on venesection, the bezoar stone, the use and properties of steel and of snow in medicine. His name is perpetuated by the botanical Monarda in Linnaeus' Class Diandria—we have several species in Canada. Charles Ecluse or L'Ecluse, who Latinized his name to Carolus Clusius, was an eminent botanist, born in Arras, France, 1526; after graduating he travelled extensively, visiting England three times and also Vienna. In 1593, he became professor of botany at Leyden and continued in that position until his death in 1609. He had all kinds of physical suffering, fevers, dropsy, fracture of right arm and leg, dislocation at the age of sixty-three of his right thigh so that he became incapacitated from walking, calculus, colic, hernia—we are not told that he had toothache, but it is likely he must have.

44. *Dolorem dentium sedat, dentibus, etiam corruptis, imposita; atque si hac dens corruptus ustuletur, prohibet ne corruptic longius serpat.*

"Ustulo," "to burn, scorch," is rare in classical Latin; it sometimes means "to crisp the hair"; in mediaeval medicine, it meant burning with the "ustura" "fer chaud," actual cautery. "Ustura" was also one of the names given to the Carbuncle.

The Tacamahaca gum seems to be of different trees: the description given of the tree fits the Mexican tree *Bursera (Elaphrum) tomentosa;* but the gum came also from other Burseras and the kindred *Protinum.* The name Tacamahac is now generally applied to the Balsam-Poplar, *Populus balsamifera.*

45. *Ad eosdem morbos laudatur quos Tacamahaca curare solst et minore tempore spacio vires suas exerit.*

The Caraña or Caranna is from the *Bursera acuminalis* of the Natural order, Amyridacaea. Phillips, (1678-1706), says of it: "Caranna, a gum coming from the West Indies, good for the Tooth-ach if applyed to the Temples." N.E.D. *sub voc.* "Carana."

The gum is described as like the Tacamahac but brighter, more fluid and heavier.

46. *Dolores dentium a causa frigida non modò sinit dente prius deterso aliquo linteo eius delibuto, et pilula ex eius folio confecta denti indita, sed etiam ne corruptio serpat, prohibet.*

47. *Dentes eodem pulveri fricati stabiliuntur, gingiuae abscedentes sanantur.* This tree grows only in one Province and is described in a letter to Monardes by Petrus de Osma et Xarayzeio from Lima, Peru. December 26, 1568.

48. *Idem commanducatus, gingiuis abscedentibus auxilio est, dentes stabilit, eosque a scabritia et corruptione liberat, orisque halitum commendat, sed postea vino os eluendum, ad amaritudinem tollendum.*

Dunglison, Dictionary of Medical Science, p. 175, says: "Carlo Sancto Radix, St. Charles Root, found in Mechoachan. The bark is aromatic, bitter and acrid. It is considered to be sudorific and to strengthen the gums and stomach."

49. *Vulnera recentia glutinat, gingiuas a putrefactione liberat et dentes stabilit. "Glutino,"* properly "to glue," is the regular medical term for closing up or uniting a wound; it is used in this sense by Celsus, who speaks of *"glutinantia medicamenta"* (VII, 4); and by Pliny, who has *"cicatracibus glutinandis" 32,* 6, 35, par. 105—see also Celsus, VII, 27, 28: Pliny, 25, 5, 19, par. 43. The French, as Dr. Dunglison says, Med. Dict., *sub voc.* "Agglutinate," use the word "agglutiner" in the sense of "to reunite." He does not seem to be aware that the word "glutinate" was used in English in the same sense—cf, "glutination," "glutinative."

Dragon's Blood is well known in drug stores.

50. *Guancauilcas vocantur cius regionis incolae et edentudli sunt, quoniam pro mori habent vt sibi dentes eximant, quos, suis idolis offerant, dicentes optima quaeque eis offerri debere hominem autem nihil praestantius, nihil magis necessarium dentibus habere.* I fancy all will agree on this estimate of the value of teeth—even if they would prefer to keep them in their mouth rather than lay them on the altar.

51. Bezoar stones are stones, calculi, found in the stomach of certain goats or deer—in America of other ruminants—they had a great name as a cureall though practically inert—they do not differ in origin from those sometimes found in the cow.

Petrus de Osma et Xarayzeio in his letter to Monardes tells of a hunt he had taken part in in June, 1568, for animals with the Bezoar stone. I translate somewhat freely:

"The form of the animal from which the Bezoar stone is obtained you have described in your book. Having made diligent inquiry we found a certain kind of animal frequenting these mountains very similar to the goats—except that they are without horns—which you say are found in East India. They are reddish in color for the most part and feed on healthgiving plants (of which there is great plenty in the mountains where these animals feed), and are so fleet that we could get them only by gunshot.

On the 25th of the present month of June, 1568, I with some friends went out to hunt on the mountains of this region: we were five days hunting and killed some of these animals of which I have spoken; as we had undertaken the hunt for them, we carried along your book.

Having made a large opening we found no stone, even in those of advanced age either in the stomach or in any other part of the body; from which we inferred that they were not similar to the (East) Indian animals. The Indians whom we had taken with us as servants being closely questioned in what part of the body these animals had the stones, said that they knew nothing about such stones (as they were most hostile to us and did not wish to disclose their secrets to us). But an Indian lad ten or twelve years old, when he saw us so anxious for this information showed us a certain receptaculum, like a pouch in the animals, in which they received the devoured herbage and after it had been ruminated sent it into the stomach. The Indians wanted to kill the boy then and there because he had shown it to us; and afterwards when we were busy hunting, they caught him and as we learned sacrificed him. The Indians set a great value on these stones and are accustomed to offer them up at the shrines of their idols which they call *Guacas*—they also offer other their most precious possessions as gold, silver, gems, necklaces, animals and boys.

(To be concluded)

ATHLETICS AND HEALTH

Athletics have been coupled, by many apologists, with the promotion of health and physical vigor. It would have been correct to say that it is the natural outcome of the possession of health and vigor, but no one can establish the first thesis on any sound basis of fact or analogy.

Athletics carry with them the idea of competition, and we go into such competitive contests either for pleasure or for financial profit. It may be that these results may possibly conduce indirectly to health and it may not—it all depends on the athletics and those who take part.

Athletics are peculiar to man, as wild animals never take to Marathon races and, in fact, keep in the best of health not by taking exercise but by letting exercise take them.

In many colleges the football, baseball and other teams are nominally a part of the physical education régime. Prominent physical directors have, however, inveighed against the policy of spending heaps of money for coaching, clothing and feeding these teams. It seemed to reflect on their own efforts at improving and maintaining the health of the rank and file of students. There is no doubt about the enormous outlay in this direction, but it is time that all concerned should divorce the college athlete and his performance from the health education work of the school, for they do not belong there, even if they happen to be under the supervision of the department of physical education and are housed in the nominal house of health—the gymnasium.

The significant expression, "we are not in this business for our health" applies literally to the members of the teams which face each other on the gridiron or basketball courts. They are in to win, for the pleasure that comes with the consciousness of either having won or of having done one's best to win. Possibly they appear, and often are, at this time in the pink of condition so far as brute health and physique are concerned, but they were selected because of the presumed possession of health and strength and they are little better than they were before training; besides, they know, and everyone else knows, they will soon lapse into their former, or a worse, state. We are not here concerned with any mental or moral values which are said to attend athletic training and practice.

A certain small percentage of college youth are endowed with such a surplus of energy that they wish to take part in these contests because they enjoy the game. A very large percentage of college youth enjoy watching the game and exercising their lungs accordingly. The result is a highly exciting, staged spectacle with a large attendance and good gate receipts. Among the producers of this spectacle are a few who have a personal liking for the drama or for music, together with considerable talent and energy enough to survive a spell of coaching along these lines. They vie with each other to do their best. They give their spectacle (concert or play) and it is attended by many who are pleased according to the performance and their own emotional or mental receptivity and response. It takes good health and some effort to reach our limits of attainment in music or in acting, and our great executants in these arts are usually men of strong physique, though this is never mentioned and such practices are never excused as means of securing health.

Save that competition and the bodily effort put forth are apparent in the playing of games and not so evident in the arts in which expression is given through vocal cords or fingers, the functions are quite comparable. For playing, or interest in, football, however, our instincts are more primitive and more universal.

Attempts have been made to show that those who have taken part in college athletics are not a healthy class in afterlife, and there are statistics to show that they are just as healthy. What we ought to expect is that they would be more healthy, not for any training for, or indulgence in, athletics, but because of the superabundance of vitality which led them originally into competitive games. But such superabundance is likely to make one less careful and conservative of health in our modern modes of living than he who must perforce husband his bodily possessions from day to day.

When we come down from the high pinnacle of pugilism, professional baseball, and college major sports to the realm where a full pocketbook, fame, or the survival of a school do not depend on his efforts—down to volley ball, tennis, golf or croquet, the same conditions and causes for action hold good except in those cases where the pupil or the patient is driven to partake by some teacher or doctor who believes the exercise will be beneficial. Provided the games are agreeable, in no way exhaust the surplus of nervous energy and counteract the compulsion and inclination to find our work and our recreation in ways too sedentary and too confining to conform to our primitive bodily functions, they are undoubtedly healthful. It is here that the physical educator finds his field of usefulness, but toward

the athlete he can only be concerned in seeing that he does not come to more harm than is to be expected and to patch up his injuries to the best of his ability. That one of these athletes should, without further knowledge and training, set himself up or be set up to advise those who do not belong, physiologically or psychologically, to his own class, is an absurd state of affairs which, happily, is passing.

DISEASE AND LITERATURE

A short time ago a distinguished writer, Richard Le Gallienne, discussed the relationship between drunkenness and drug taking and high imaginative literary powers. That there is a relationship seems evident from looking over the names of some of those who have won a place in the first ranks of writers.

Edgar Allan Poe is the greatest of imaginative writers who was both a genius and a dipsomaniac. He was also the one who combined this wonderful gift with this unfortunate taint in the highest degree. He soared to the loftiest flights of imagination with the power of expressing them in the most apt and beautiful language and sunk to the lowest depths of mental and social degradation. Undoubtedly in the case of Poe it was a disease in that he had inherited a highly strung nervous temperament and was peculiarly susceptible to the influence of alcohol. He was a psychopath driven at recurring periods to drink alcohol to excess due to the reaction produced by the stress of mental effort.

Coleridge, though physically vigorous and strong, was of unstable temperament and sought forgetfulness of this world's worries and a transference into the world of dreams by indulging in narcotics.

De Quincey discovered his nepenthe in opium of which he had habituated himself to take prodigious quantities, but he lived to be more than eighty years old and almost to the last wrote fluently, logically and clearly.

Swinburne, up to a certain time of his life, drank freely, and so little did this habit interfere with his flights of imagination or of diction and expression that his loveliest poetry was written at this period of his career. Indeed, it has been said that when Watts Dunton succeeded in weaning him from this feeling that he, Swinburne, wrote nothing of note afterwards.

Le Gallienne probes the problem of the relationship between drinking and drug taking and high literary efforts from the aspect of its effect or influence upon the standard of the output, and appears to decide that the effect on the whole was favorable. From the point of view of disease and literature it seems likely that all the men mentioned, and they are but a few among the many of like mental gifts and perversions, were abnormal in mental makeup and in temperament. While not subscribing to the opinion of Max Nordau that genius is akin to degeneration, it does appear certain that many of the most brilliant literary men and women deviate from the normal, to an extent, sometimes allied to disease. There is truth in Dryden's line, "Great wits are oft to madness close allied."

However, there is one disease which does quicken the wits at the same time that it wastes the body, while the mental powers remain normal. Stevenson, Keats, Hood and probably Emily Brontë were among the conspicuous examples of how seemingly pulmonary tuberculosis does stimulate the mental faculties. No doubt the introspection of the invalid must be taken into consideration, the fact that the sufferer from tuberculosis or of other disease is precluded from taking part in those violent forms of exercise natural to the man physically sound, and that he or she must seek relief from the monotony of existence in mental exercise of some description. The powers of imagination fostered by introspection are afforded ample opportunities for expressing themselves and in literature these powers frequently find the necessary outlet.

These remarks may be applied to any form of disease that prevents the individual from leading the ordinary life of civilization or of following his bent in travel or adventure. But it has been asserted that pulmonary tuberculosis stands in this respect somewhat apart from other diseases, and that there is a something in the germ and factors which produce it that urge its victims to mental efforts of one sort or another, and as the choice is limited and writing is perhaps the easiest for them, to literature they turn. There is no disease in which the powers of the mind are clearer than in tuberculosis, and it is possible that the malady acts as a strong stimulant on the mind and the imagination.

A further question arises, are the writings of a diseased man healthy writings or are they not often the outpourings of a mind diseased? It is true that morbid fancies and unpleasant evidences of unhealthy sensibilities are exhibited throughout the books of sick men and women. Poe was morbid to an extreme degree and his imagination at times uncontrolled. Emily Brontë's writings for the most part consisted of almost incoherent sentences interspersed with flashes of true genius. It may be concluded that there is a relationship between disease and literature of the highest stamp, although it may be also said that at the present time there is a great deal of diseased socalled literature in which no trace of genius can be found. The evidence in support of a relationship between pulmonary tuberculosis and literary genius and talent is strong, but it must be borne in mind that having tuberculosis of course does not in itself confer genius.

or even talent, but may and apparently does stimulate the mental powers. The question as to whether genius or exceptional mental powers, especially those of the imagination, are more often present in the tuberculous than the normal individual is a moot one and is possibly worthy of further study. Although tuberculosis or any disease is not to be desired, it is perhaps well that in this material age there should be some who can exercise their vivid imaginations for the relief and relaxation of those who are compelled to lead a humdrum existence. Writing, too, is a compensation, to some extent, to the invalid for pleasures missed, and from the psychotherapeutic point of view affords occupation and provides a vent for some of the mass of emotional feelings which have collected during his long hours of introspection and threaten to surcharge his brain. It acts in a way similar to psychoanalysis.

MASTITIS IN THE MALE

In male subjects between eighteen and twenty-one years of age one not infrequently meets with a semi-physiological hypertrophy of the breast which sometimes is bilateral and must not be confounded with fibrous hypertrophy which is a far less common process. From the viewpoint of symptomatology, it will be found that one or both nipples have increased in size giving rise to pain which, at first, is indefinite, but later becomes shooting in character and increased by contact with the clothing to such an extent as to become almost intolerable. The breast may increase in size to the extent of those of a girl of sixteen. Palpation reveals a tumor varying in size from a walnut to an orange and firm to the feel. The centre of the tumefaction corresponds to the areola; the skin is freely movable over the tumor and the latter is not adherent to the underlying structures. Occasionally there is an appreciable hypertrophy of the regional lymphnodes.

Regardless of the oft expressed opinion, this mammary hypertrophy does not in the majority of cases coincide with atrophy of the testicles, and signs of degeneration or infantilism are never observed. On the other hand, some type of infection will be found to be the etiological factor in most cases, the mastitis developing after a severe form of influenza, measles, secondary syphilis, streptococcal infections of the joints or pulmonary tuberculosis. The mastitis does not go on to supuration and its prognosis may be regarded as benign.

As to treatment reliance should be placed on diathermy, heliotherapy, slight methodical compression combined with the usual treatment of convalescents from serious infectious processes and specific treatment when the subject is syphilitic. One must never expect *restitutio ad integrum*, because a slight hypertrophy will invariably remain. It may occasionally happen that excision of the tumor will be required.

ERUCTATIONS

"Take heed, Sancho, not to chew on both sides of thy mouth at once, and by no means to eruct before company." "I know not what you mean by *eruct*," quoth Sancho. "To eruct," said Don Quixote, "means to belch—a filthy, though very significant word; and therefore, the polite, instead of saying 'belch,' make use of the word 'eruct,' which is borrowed from the Latin; and from belchings they say 'eructations,' and though it is true that some do not yet understand these terms, it matters not much, for in time by use and custom their meaning will be known to all."

Works on diseases of digestion are most disappointing to the average physician and the more exhaustive they are the more disappointing. They contain a great many words about ulcer, cancer, and gastroenteritis and the like, a great deal about test meals and stomach examinations, but little about that most common of all ailments, dyspepsia. There is hardly mention of either belching or eructation or of discharges of gas from the lower end of the food canal and not much said about the troublesome gases which one would like to discharge but cannot.

If anything is suggested by the treatise by way of therapeusis for these annoying and sometimes distressing conditions, it is almost invariably some palliative which is assigned to the heroic task.

Man is the only animal given to eructation, though some of his domesticated friends become gas factories in proportion as they take in a similar sort of food. Fermenting food, whether in the receptacle near the beginning or the end of the food tract, means overwork of the chemical laboratories connected therewith, for it is inconceivable that such accumulations of gas can be normal. Ten to one the clinician prescribes hydrochloric acid or a digestive tablet when the only logical thing to do is to remove the needless task thrown on these organs of digestion. A fast of one meal or of a day makes a good beginning. The quantity of all kinds of food may not be too great, but the carbohydrates have been usually much overingested. While it is usually the Sanchos and those who "chew on both sides" that eruct, the Quixotes may also suffer occasionally from indigestion through an overconcern with the affairs of life. This psychic dyspepsia is more difficult to cure.

It is in the management of these cases of common everyday disorders of digestion that the average physician needs his knowledge of physiology and of nutrition and to exercise his commonsense. The whole pharmacopœia is not likely to be of much assistance to him or his patient.

Vanderbilt University's New $3,000,000 Medical School

GEORGE E. SIMMONS
Nashville, Tenn.

Deprecation of the antagonism which has sprung up between public health officers and practitioners featured the addresses by Dr. William H. Welch, director of the Johns Hopkins school of hygiene and public health, and Dr. Simon Flexner, director of the laboratories of Rockefeller Institute for Medical Research, at the formal opening here of Vanderbilt University's new $3,000,000 medical school, October 15, 1925.

Leading physicians and surgeons, together with scores of other educators, from throughout the United States and several foreign countries assembled here for the university's semicentennial celebration, of which opening of the medical school featured the first day.

Dr. Flexner and Dr. Welch addressed the medical conference, and were among those who inspected Vanderbilt's new school and hospital, as well as the school for nurses.

"There is nothing more disgusting to me than the antagonism which has sprung up between physicians and public health officers," Dr. Welch declared. "For the moment the matter is serious, although it is only a temporary episode and will pass away. The heart of the medical profession is sound, and I am sure this incident will pass over."

Dr. Welch, who represented also the National Academy of Sciences at the semicentennial celebration, congratulated Dean G. Canby Robinson of the new school, upon the arrangement and equipment of the Vanderbilt plant.

"Thirty years ago began a golden era for medicine," said Dr. Welch, "and this was especially emphasized in bacteriological work. The inspiration still exists today, but along new lines of approach to opening up the application of those discoveries. . . .

"Inspiration varies, but the highest type of research is occasioned by the desire to know the truth. Practical application is a good motive, but the highest motive is the discovery of truth in this vast exploration of nature.

"I believe in the emancipation of clinical medicine," he said. "The clinical laboratory problems are presented by living patients. Heretofore, clinical medicine has been too much under the domination of laboratory subjects."

Dr. Flexner, a research worker of wide fame, congratulated the university upon its new medical school and its opportunity for service to science.

"Such a preparation as this to serve science is an event of national if not international importance," he declared. It remains to be seen what assistance the city and state will give it—and I refer to spiritual rather than material assistance."

He contrasted nineteenth century medical study with the present day methods. In that era, he said, the study of medicine consisted largely in consultation of texts, but a new day has dawned, with its practical training in the hospital and its extension of knowledge through research. That more advanced method has become a part of the Nashville school.

George M. Vincent, president of the Rockefeller Foundation of New York, also took occasion to discuss the medical school at length. His address was delivered before the session of delegates Thursday night. He warned the men of science to be aware of what the public would think of them.

"This medical centre," said Dr. Vincent, "is part of a far flung system of university schools, which extends from Baltimore, Philadelphia, New York and Boston to San Francisco; from Montreal and Toronto to New Orleans. . . .

"This medical school, then, placed in the midst of a great region, manned by a well trained staff who

work under favorable conditions of housing, equipment and hospital facilities, is committed to the scientific method and is actuated by the scientific spirit. . . . Here the knowledge already available through the progress of medical research will be used for the healing of the sick, the teaching of physicians and the training of investigators. . . .

"But too much must not be taken for granted. The attitude of the American public towards science is often disturbing. The average citizen seems impressed by what are glibly called the marvels of mechanical progress. He reads of the wizards of invention. Science takes on an almost magical character. It is not easy for the public to carry over from mechanical achievement the idea of scientific method applied to the human body and mind. Too great an expectation of results is very frequently aroused.

"There is also a tendency to undue simplification, which encourages belief in bizarre cures and panaceas. The old frontier tradition still persists; the jack of all trades is extolled as the typical versatile American.

"It must be admitted that the man in the street is not wholly to blame if he is distrustful of specialists. The spectacle of experts in court testifying often in support of diametrically opposed ideas is not lost upon the public. . . . To abuse great groups of people for their attitudes and conduct is like upbraiding the weather. Sometimes Christians are twitted with failure to display the Christian virtues. Scientists are not free from a similar fault. The scientific spirit is calm, dispassionate, detached, objective, but they seem to forget that.

"By sympathetic comradeship with the medical profession, by occasional contact with groups of laymen, by social intercourse, by public address, the men and women of this institution may create a sympathetic appreciation of the aims and achievements, as well as the baffling difficulties, of modern medicine."

There was no expression of fear, on the part of academic leaders and notable educators visiting Vanderbilt University, that the medical school might overshadow other parts of the university within a few years. This fear was expressed last spring by the president of the university's board of trust, but apparently was not in the minds of those who took part in the formal opening of the medical school.

The new Vanderbilt school has an imposing four story brick structure—a group of buildings linked in a unit—with ample space for the hospital, class rooms, laboratories, library, offices and the like. It is the most complete and commodius, educators say, in this section of the country.

Dean Robinson, head of the school, is a graduate of Johns Hopkins University and a former professor at Washington University, St. Louis.

Philadelphia Meeting of the American College of Surgeons

On the first five days of the week beginning October 26th the American College of Surgeons held their meeting in the Hotel Bellevue-Stratford, Philadelphia. Some of its more distinctive features can be set down. An important conference was held on hospital standardization which was opened by the retiring president of the college, Dr. Charles Mayo. Dr. Franklin H. Martin, Chicago, director general of the college, presented the eighth annual report on hospital standardization. The report showed that while great improvement has been made in improving conditions of hospitals in this country, there yet remains much to be done.

On the evening of Monday, October 26th, the president elect, Dr. Rudolf Matas, of New Orleans, was inducted, Dr. Charles Mayo gave his address, Dr. Charles Nassau, of Philadelphia, welcomed the guests to the city of brotherly love, and Sir Arbuthnot Lane, the well known London surgeon, gave the Murphy oration. In introducing the English surgeon Dr. Matas compared the ideals and careers of Murphy and Lane, pointing out that they were both distinguished by originality of thought and execution. They were neither of them content to follow the beaten track, they not only improved existing surgical methods but devised new ones. Dr. Matas thought that they were, perhaps, the greatest surgeons of their generation.

Sir Arbuthnot Lane said, in part, that he felt and appreciated deeply the honor of being asked to give the Murphy oration. Like them all he loved that great, big hearted, generous man, who was so full of enthusiasm and energy. Though seriously handicapped by feeble health he never allowed anything to interfere with the work in which he took so much pride and interest that he thereby materially shortened his life. He, Sir Arbuthnot Lane, was very fortunate in making Dr. Murphy's acquaintance many years ago, owing to having obtained one of his buttons and having used it successfully six months before anyone in England. The case was published in the *Lancet* early in 1894. Learning of this Dr. Murphy, accompanied by his beautiful wife, called to congratulate him on the result he had obtained by the use of this most ingenious and useful device. How many lives that button had saved and how much it had stimulated surgeons to improve their technic was well known to all. It had proved to be one of the greatest advances in abdominal surgery. There were still conditions in which no other method could approach the Murphy button in usefulness. Up to that time the name of Murphy was practically unknown in Europe. Their friendship dated from that visit and he had always regarded it as a great privilege to have since had many opportunities of discussing surgical problems with one with whom he was entirely in sympathy. He was always so ready to take an active interest in any new problem on which

his fertile and active brain invariably cast some fresh light. He was essentially an original man, as well as being a superb teacher.

Sir Arbuthnot Lane knew, as did so many of his intimate friends, how much Murphy owed to the constant care and devotion of his charming helpmate, who seemed to possess the secret of perennial youth. While unable to control his indomitable will in the pursuit of science she did her utmost to provide him with the care and attention necessary to enable him to continue his arduous occupation. Not only did she look after his health but she took a very active interest in his surgical work. Although many years had elapsed, he could vividly remember her description of the manner in which the button was evolved and the anxiety and interest with which they both watched the result of its use in animals before employing it in the human subject. Her love and care played no small part in making Murphy's career the great success it was.

What struck Sir Arbuthnot Lane most in Murphy was his wonderful generosity, a quality which is so largely shared by other American surgeons. He was always most anxious to accord praise to others wherever it was possible and often avoided claiming for himself much original investigation work for which he was largely responsible. The excellence of his surgical work appealed to everyone, as also did his remarkable breadth of vision and foresight.

He possessed in a peculiar degree the power to hold and hypnotize his audience beyond that of any other surgeon he had met. He appeared to take possession of his hearers and to imbue them with a feeling that whatever he said was true. Few of them would forget his operations and his demonstrations in the theatre. Geniuses of the type of Murphy were not teachers in the ordinary sense in that they did not produce the like among their immediate entourage but, on the other hand, they exerted an immense and widespread influence upon the whole community. That was essentially the case with Murphy.

Sir Arbuthnot Lane spent much time with Dr. Murphy during that memorable conference in London in 1914, of which he was the distinguished president, when they had many conversations about chronic intestinal stasis in which he took an active interest and for which he foretold a great future. At that time not only did few people accept my views on this subject but the bitterness of the attacks of many members of the profession was characteristic of their usual attitude towards any ideas with which they were not familiar. Murphy was infinitely more practical. He saw a large number of such cases both before and after operation, he was present at many operations and he investigated the histories of these patients in his usual thorough manner. He was one of those who accepted my views and gave me hearty encouragement. He was also glad to remember that he took precisely the same attitude when the operative treatment of simple fractures was being opposed in the usual acrimonious manner.

After reading a portion of the last letter Sir Arbuthnot Lane received from Dr. Murphy, the speaker discussed at considerable length the subject of intestinal stasis but from the preventive viewpoint, arguing that it was a disease of civilization which could be avoided by living more simply in every way and especially so far as diet was concerned, that is diet from infancy up. Sir Arbuthnot Lane emphasized the point that the public must be educated as to how disease might be largely prevented by living properly and embraced the occasion to introduce to an American audience a new society which has been established in Great Britain to educate the public in the several principles which he has been teaching for years. He suggested that a similar society should be found in America called The New Health Society and dedicated to the memory of Murphy.

Dr. Matas in his presidential address fulminated against the quacks and charlatans who attempted to mulct a too credulous public. He said in part that with the central, communal hospital, staffed by a competent group of clinical and laboratory specialists, would come a safe resort for whoever might be in need of medical help and the demand for the family physician would cease. A new type of doctor would arise whose functions would still be those of an intermediary between patient and specialist, but who, apart from his classifying and diagnostic functions, would find his chief occupation as a sanitary adviser and public health officer. This outlook would probably be disputed, but coming events cast their shadows before, and there could be no doubt that this was the meaning of the shadow now seen.

Lord Dawson, of Penn, physician to the King of England, and one of the distinguished guests, in urging a hospital for every community no matter how rural, said that the family doctor should remain the foundation of medical service, but his outlook, functions and training needed modification to meet changing needs. First, must come his care of the sick, but beyond that he will have communal and educational duties. He suggested that in the future the doctors of a district would form themselves into a faculty which would place the varieties of knowledge and experience of its members at the service of the community and in its collective capacity exercise a powerful and much needed influence on public life. The members of this local faculty could best hold high their standards of work by the hospital. He should like to see the conception of the hospital widened to that of a health centre where curative work, clinic, wards, communal service and educational facilities could find a home.

Another distinguished guest was Thierry de Martel, professor of neurology in the University of Paris. On the last evening of the congress, Friday, October 30th, fellowships were given. There were 533 candidates. Honorary fellowships were given to Lord Dawson of Penn, Sir William Arbuthnot Lane and Dr. Philip Franklin both of London, Dr. William Blair Bell of Liverpool, Dr. William H. Garmalt of Yale University, and Dr. Frederick S. Dennis of New York City. The order of Chevalier of the Legion of Honor was bestowed on Dr. Charles Mayo by Dr. Thierry de Martel. Dr. Vittorino Putti, of Bologna, Italy, was accorded the fellowship.

At the annual meeting on the afternoon of October 29th, Dr. Walter W. Chipman, professor of gynecology and obstetrics in McGill University, Montreal, was elected president. Dr. Charles Starr, professor of surgery in the University of Toronto, was elected first vice-president, and Dr. Charles Nassau, of Philadelphia, second vice-president.

News Items.

Red Cross Roll Call.—The physicians and surgeons have been mobilized for the ninth annual roll call of the American Red Cross under the leadership of Dr. Robert G. Reese. The drive began on Armistice Day, November 11th.

Park View Hospital.—This institution, located on upper Fifth Avenue, New York, has acquired an adjacent building to be used in the care of ear, nose and throat cases.

Bequest for Tropical Medicine.—A chair of tropical medicine is to be established at Tulane University School of Medicine, New Orleans, through a bequest of $60,000 from William E. Vincent. Dr. Aldo Castellani, of the London School of Tropical Medicine, is to be the head of the new department.

Thyroid Study.—A survey of the extent of thyroid enlargement and its relation to focal infection is to be made by the Public Health Service in several cities of Connecticut. Examinations will be made of school children.

Wyoming Medical Licenses.—The Wyoming Board of Medical Examiners announces that only graduates of Class A medical colleges will be recognized as applicants for licenses.

Celebration of Royal College of Physicians.—To mark a century in the occupancy of its present building, this association recently held a special meeting in London. The college was founded by Thomas Linacre, and its charter is dated 1518.

Survey of Potomac River.—A sanitary survey of the Potomac River in the vicinity of Washington, with a view to making it safe for bathing, has been undertaken by the Public Health Service and the District health officer, Dr. William C. Fowler.

Community Nursing Service.—A new law in Illinois provides that cities from five to ten thousand in population may levy taxes to provide community nurses, such nurses to be appointed by the mayor on recommendation of the local board of health.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the Alvarenga Prize for 1925 has been awarded to Dr. Raphael Isaacs, of Boston, for his essay on the Nature of the Action of the Röntgen Rays on Living Tissue. Essays for the prize award of 1926 must be submitted to the secretary of the College by May 1st; any subject in medicine may be selected but the article cannot have been published before.

Personal.—Dr. Smith Ely Jelliffe has just returned to New York to resume his practice after attending the International Meeting of Psychoanalysts in Bad Homburg and the German Society of Psychiatrists and Neurologists in Cassel. He also visited the neurological and psychiatric clinics of Amsterdam, Vienna, Padua, Milan and Genoa.

Dr. Charles F. Read, the former superintendent of the Chicago State Hospital, is the new head of the department of nervous and mental diseases of the Loyola University Medical School.

Dr. Harvey Cushing, of Harvard, delivered the Cameron Prize Lectures of the University of Edinburgh.

Dr. Charles H. Keene, of the Pennsylvania Department of Public Education, has resigned to become director of physical education of the University of Buffalo.

Dr. Robert H. Babcock, of Chicago, was honored with a dinner recently at the Drake Hotel.

Dr. George H. Bigelow has been appointed state commissioner of public health of Massachusetts.

Lord Bertram Dawson, physician to the King of England, Dr. Charles H. Mayo, of Rochester, and Dr. Rudolph Matas, of New Orleans, have been awarded the honorary degree of Doctor of Science by the University of Pennsylvania.

Dr. Chester C. Kirk has been appointed superintendent of the State Institution for the Feebleminded at Orient, Ohio. Doctor Kirk has been assistant superintendent of the Toledo Hospital, and professor of nervous and mental diseases, University of Arkansas School of Medicine.

Tufts College Medical School announces the appointment of Dr. Charles F. Painter as head of the department of history of medicine, and Dr. Mark H. Rogers, head of the department of orthopedic surgery.

Dr. John R. Whisemant of New York has been appointed urologist of the Tarrytown Hospital, Tarrytown, New York.

Gerhard Medal.—Dr. William H. Welch of Johns Hopkins, is the first recipient of the W. W. Gerhard gold medal of the Pathological Society of Philadelphia. This medal is established by Dr. Arthur H. Gerhard, in memory of William Wood Gerhard, who first distinguished the difference between typhoid and typhus fever.

Agamede Medal.—The Woman's Foundation for Health has established the Agamede Gold Medal, to be awarded annually to that woman citizen of the United States who has performed during the year the most distinguished service in the promotion of the health and happiness of American women.

Medical Charity.—The Federation for the Support of Jewish Philanthropic Societies of New York reports it will require a total of $981,650 to finance its medical charities. The institutions include Beth Israel Hospital, Hospital for Joint Diseases, Jewish Maternity Hospital, Lebanon Hospital, Montefiore Hospital, Bedford Sanatorium, Mount Sinai Hospital, and Stony Wold Sanatorium.

Gifts and Bequests.—The will of the late James B. Duke provides among his other bequests to Duke University, $10,000,000 for the medical school and hospital.

The estate of Julia Mayer provides $100,000 for the Jewish Hospital Association of Philadelphia.

The will of Simon R. Weil provides about $80,000 each for Mount Sinai, Presbyterian, Skin and Cancer, and the Hospital for the Ruptured and Crippled, New York.

The New York Orthopedic Dispensary and Hospital is to receive the residuary estate of Mrs. Caroline James, of Northport, Long Island, in amount about $300,000.

The Fifth Avenue Hospital, New York, is to receive $1,000,000 from the estate of Thomas Franklin Manville.

Postgraduate Classes in Stomatology.—The following courses, given under the auspices of the American Stomatological Association, are open to duly licensed physicians and dentists: stomatological bacteriology, under the supervision of Dr. William H. Park and Dr. Charles Krumweide; diagnoses and focal infection, Dr. G. Reese Satterlee, Dr. Homer E. Smith, Dr. George A. Wyeth and others; stomatological hygiene, Dr. Alfred J. Asgis and E. B. Hardisty; dietetics in stomatological practice, Dr. Holmes C. Jackson; clinical dietetics, Dr. Robert H. Rose. Clinical and laboratory courses will be given under the respective instructors in charge at the following institutions: Fordham Hospital; University and Bellevue Medical College; Medical Laboratories; Midtown Hospital, etc. For information, write to the director of classes, Aeolian Hall, 33 West Forty-second Street, New York City.

Hospital News.—The Jewish Maternity Hospital, New York, is conducting a campaign to raise $1,250,000.

The Bronx Hospital, New York, is conducting a campaign for $1,000,000 for a new building.

The Brooklyn Cancer Institute of the Cumberland Hospital opened November 2nd, with accommodations for thirty-five patients. Dr. Charles A. Brown is the director, and Dr. John J. Gainey, Dr. George F. Herrity, and Dr. H. Fromm are his associates. Many well known physicians are serving as a consultant staff.

The cornerstone of the new Caledonian Hospital in Brooklyn has been laid.

The Brooklyn State Hospital will erect fifteen new buildings at Creedmoor, Long Island, at a cost of $4,000,000.

The Babies' and Children's Hospital and the maternity Hospital of Cleveland have been dedicated, Abraham Flexner of the Rockefeller Foundation giving the address. These hospitals have each built new seven story buildings near the School of Medicine of Western Reserve University. In addition, the Lakeside Hospital and the Rainbow Hospital for Crippled Children will be affiliated with the medical and nursing schools of Western Reserve, all functioning as the University Hospital, thus carrying out one of the recommendations of the Hospital and Health Survey conducted by the Cleveland Hospital Council four years ago.

St. Joseph's Mercy Hospital of Ann Arbor, Michigan, is building a $100,000 unit for psychopathic patients.

Cook County Hospital, Chicago, is planning a $2,500,000 addition.

St. Margaret's Hospital, Hammond, Indiana, has dedicated a new wing, built at a cost of $750,000, and containing 325 beds.

The Herman Kiefer Municipal Hospital of Detroit is planning a $3,000,000 addition.

Society News and Notes.

The New York Academy of Medicine will hold an exhibit of the work of Charcot, beginning November 25th.

The Emergency Tuberculosis Relief Committee of New York City secured for the night of November 17th the performance of Charlot's Revue of 1926 as an aid to its work. The chief object of the organization is to provide temporary relief for all deserving persons and the members of their families when threatened with or suffering from tuberculosis.

* * *

At the regular meeting on Friday, November 6th, of the Brooklyn Institute of Arts and Sciences, Dr. Ira S. Wile spoke on the subject of early childhood as determining the future health and success of the individual.

* * *

The British press has recently announced the organization of a society aiming to bring about a "golden age" of health in England. This association will be formally inaugurated early in December and will be known as the New Health Society. Prevention of disease will be its chief line of work. A nationwide propaganda for its launching is being undertaken. The instigators are said to be a number of prominent British medical men and hygienists, and the society will have the backing of three former Prime Ministers, the Earl of Oxford and Asquith, the Earl of Balfour. and Ramsay MacDonald.

* * *

A health and tuberculosis conference was held in New York, November 19th and 20th, by the New York Tuberculosis and Health Association, the Milbank Memorial Fund, the State Charities Aid Association, and the city and state health departments. Representatives from the entire state were present. Addresses were given by Surgeon General Cumming, of the Public Health Service, Dr. Matthias Nicoll, Jr., Dr. Frank P. Monaghan, Dr. Floyd C. Haviland, Dr. Sanger Brown, and Dr. William H. Welch.

* * *

At the recent meeting of the American Hospital Association, held at Louisville, Ky., Dr. Arthur C. Bachmeyer, of Cincinnati, was installed as president. Dr. Richard G. Broderick, of San Leandro, Calif., was made president-elect; Dr. Walter H. Conley, of New York, Miss Blanche M. Fuller, of Omaha, and Mr. Wallace W. Kenney, of Halifax, vice-presidents; Dr. William H. Walsh, of Chicago, executive secretary, and Mr. Asa S. Bacon, of Chicago, treasurer.

* * *

The following are the new officers of the American Public Health Association: President, Dr. Charles-Edward A. Winslow, of New Haven; vice-presidents, Dr. John A. Amyot of Ottawa, Dr. Max C. Starkloff of St. Louis, and Dr. Albert J. Chesley of Minneapolis, and Dr. Louis I. Dublin of New York.

* * *

The meeting of the Clinical Society of the Hospital for Joint Diseases on Tuesday evening, November 24th, will be devoted to addresses on Chronic Arthritis, Medical Aspects by Dr. William E. Preble of Boston; Surgical Aspects (includidng ankylosis) with moving picture of arthroplasty, by Dr. William Russell MacAusland of Boston. Members of the profession are welcome.

* * *

The American Electrotherapeutic Association held its annual meeting recently in Chicago. The presidential address was delivered by Dr. William T. Johnson, of Philadelphia, on Factors in the Establishment of Sound Physiotherapy Practice. The papers were grouped on the subjects of phototherapy, x ray and radium therapy, hydrotherapy and thermotherapy, high frequency therapy, static electricity, and the teaching and application of physical therapeutics. A clinic was held at the Cook County Hospital. The following officers were elected: President, Dr. Victor C. Pedersen, of New York; vice-presidents, Dr. Tilman Howard Plank, of Chicago, Dr. Harry E. Stewart of New Haven, Dr. Norman E. Titus of New York, Dr. George J. Ott of Boston, and Dr. Curran Pope of Louisville; treasurer, Dr. John W. Travell, of New York, and secretary, Dr. Richard Kovacs, of New York.

* * *

An intensified antituberculosis campaign has been inaugurated by the forty-six public health and social welfare organizations comprising the Council of Lower West Side Agencies of New York City. The work will cover the tenement districts from Fourteenth Street south to the Battery. Popular lectures will be arranged and literature distributed through the Bowling Green Neighborhood Association and Greenwich House.

* * *

The skull of the earliest known citizen of London has recently been discovered and introduced in an interesting lecture by Prof. Elliot Smith and Dr. Dawson to the British Zoological Society at a recent meeting of that organization. Although only part of the skull was found, it was possible to tell that it belonged to a woman of about fifty, and that she was lefthanded—this from certain indentations in the bones. The skull was found twenty-six feet below road level in absolutely disturbed gravel of Pleistocene times, and in the same layers in which the prehistoric woolly rhinoceros remains were found. The lady, according to the scientists, was closely related to the Piltsdown and Neanderthal men, popularly considered the "missing links" because of their apelike cranial characteristics.

* * *

The New York Electrotherapeutic Society met on November 4th at the Academy of Medicine. Dr. Richard Kovacs gave an interesting report of the thirty-fifth annual meeting of the American Electrotherapeutic Association recently held in Chicago, and Dr. Norman E. Titus spoke on the International Congress on Radiology and Physiotherapy in London. The paper of the evening, on Diathermy in Gonorrhea, was read by Elkin P. Cumberbatch, M.R.C.P., of London.

* * *

Dr. Aher M. Pennell, née Sorabji, of India, recently arrived in New York City, where she visited various medical institutions of note.

* * *

At the meeting of the New York Microscopical Society on November 6th at the American Museum of Natural History, Dr. William W. Browne gave an interesting address on the Rôle of the Microscope in Modern Bacteriology.

* * *

Meetings at the Academy of Medicine during the first half of November included that of the Academy itself on November 5th, at which Dr. Max Goldstein, of St. Louis, gave a practical demonstration of modern pedagogic methods in the training of the deaf child by teachers and pupils of the Central Institute for the Deaf of St. Louis; the Section of Dermatology and Syphilis met on November 4th, when patients were presented by Drs. Lapowski, Walzer and others; the Section of Neurology and Psychiatry at its meeting on the 10th presented a program arranged in cooperation with the New York Neurological Society and consisting of cases presented by Drs. Riley and Rombold, and papers by Drs. Foster Kennedy, Folsom, Kirby and Grimberg; the Section of Pediatrics, which met on the 12th, enjoyed papers by Drs. Bass, Carp, and Levene. The anniversary discourse will be on the subject of The Doctor and the Changing Order, and will be delivered on November 19th, by Dr. George E. Vincent. The second lecture of the series of the Harvey Society was given by Dr. John Northrup, of the Rockefeller Institute for Medical Research on November 14th. The subject was Pepsin and Trysin.

Other recent meetings of interest in New York were the first annual convention of the New York Pharmaceutical Conference, held during the last week of October; and the thirty-fifth annual meeting of the New York and New England Association of Railway Surgeons, held at the Hotel Commodore, November 5th and 6th the principal speakers including Drs. J. E. J. King, of New York City; F. Park Lewis, of Buffalo; W. L. Estes, Jr., of Bethlehem, Pa.; George M. Cady, of Oswego, N. Y.; Joshua Sweet, of Philadelphia, and J. L. Bower, also of Philadelphia.

Book Reviews

SURGERY OF TUBERCULOSIS

The Surgery of Pulmonary Tuberculosis. By John Alexander, B.S., M.A., M.D., Assistant Professor of Surgery in the Medical School, University of Michigan. Illustrated with fifty-three engravings and twelve plates. Philadelphia: Lea & Febiger, 1925. Pp. 356.

The introductions to this book are written by the eminent Dr. Hugh Cabot, professor of surgery at the University of Michigan, and the equally eminent phthisiotherapeutist, Dr. Edward R. Baldwin, director of the Trudeau Foundation and Trudeau School of Tuberculosis of Saranac Lake, and they show the timeliness of such a work, which is virtually the first American textbook—for such it may justly be called—on the surgery of pulmonary tuberculosis. In the first chapter, which is entitled Perspective of the Surgery of Pulmonary Tuberculosis, he justly points out that at the present time relatively few cases of pulmonary tuberculosis receive the benefit of surgery. Surprising and certainly encouraging are the statistics quoted, according to which of the surgically treated cases in all countries in recent years thirty-seven per cent. of the patients have actually been cured, and another twenty-four per cent. decidedly improved; the operative mortality was 1.5 per cent., and the additional mortality during the first six weeks only twelve per cent. The remaining nineteen per cent. includes deaths that had no connection with the operation, most of them caused by progression of the disease in the unoperated lung. No account is given of the remaining 1.5 per cent. to complete the hundred.

In describing the evolution of surgical therapy, the author discusses the cavity drainage and direct medication of tuberculous lesions. The Freud operation, which consisted of the partial resection of the first cartilage, in order to mobilize the apex, Dr. Alexander relegates as antiquated. He also speaks unfavorably of pulmonary resection and then describes the various modern operations which do not affect the tuberculous lesions directly but influence them favorably by resting and relaxing or compressing the lung. In chronological order the author traces these methods, giving full credit to the originators of the various operations, and makes this chapter most interesting by giving the portraits of the eminent surgeons who have been pathfinders in each method. Among these are De Cereville, Brauer, Gourdet, Wilms, Sauerbruch, Tuffier, Jacobaeus, Stuertz, Archibald, Bull, Saugman, Gekler, Davies, Berard, Key, and Sayago. Gekler is the only American mentioned and Archibald the only Canadian. It is regrettable that no mention is made even of the name of Murphy who, with Forlanini, must be considered the inventor of artificial pneumothorax, one of the most important modern surgical means to give local rest to the afflicted lung.

In the chapter on evolution, the author mentions among other things the extrapleural pneumolysis. The most widely used method for this procedure is that of Tuffier who, in 1910, for the first time filled the extrapleural hole made by the pneumolysis operation, using the free human fat graft. Others are using paraffin and pedicled grafts of the pectoral muscles. Concerning phrenicotomy, the author says that it may prove a valuable procedure for patients too ill for thoracoplasty. Under nonsurgical mechanical therapy are mentioned Stewart's splint, Golden's plaster of Paris jacket, and Knopf's controlled diaphragmatic breathing, or conscious bradypnea, and recommended as valuable adjuvants in the usual sanatorium treatment. Dr. Alexander, however, prefers artificial pneumothorax or thoracoplasty when they are indicated as a more sure cure. The pathological anatomy and physiology of pulmonary compression he sums up by saying, "Pulmonary compression constitutes a physiological amputation, stagnant secretions are removed and are succeeded by nonspecific inflammation and encapsulation of tuberculous lesions and profused poliferation of fibrous tissue."

Under indications and contraindications valuable statistics are offered. Saugman considers only four to eight per cent. of his tuberculous patients can be benefited by surgical therapy; Zeigler, on the other hand, found that he had recommended twenty per cent. of his six hundred patients to be operated upon by thoracoplasty, exclusive of phrenicotomy. The author very wisely says that the indications for surgery are considerably more strict than for pneumothorax, and not all those cases in which pneumothorax fails are fit for operation. Somewhat astounding is the statement that "In spite of the fact that the operation of artificial pneumothorax *per se* is safer than that of thoracoplasty *per se,* there is a rapidly growing sentiment among those experienced with both methods that thoracoplasty should be used in preference to pneumothorax, even a complete one, for a large group of selected cases." It would seem that a more lengthy experience and more extensive reports from all countries, from phthisiotherapeutists as well as surgeons, should be brought together before thoracoplasty should be given the preference over artificial pneumothorax in the average tuberculous case needing compression.

Jacobaeus's operation for cutting pleuritic adhesions with the aid of a thoracoscope and an electric cautery, finds little favor with this author, but he describes and illustrates it most fully. He comes to the conclusion that Jacobaeus's operation is valuable and safe when the adhesions are thin and cordlike, but dangerous when they are thick and extensive. He believes that "If a satisfactory pneumothorax cannot be attained by a relatively simple operation of short duration both cauterization and pneumothorax should be abandoned and thoracoplasty performed."

Before describing in detail the well known Wilms-Sauerbruch extrapleural paravertebral thoracoplasty, Dr. Alexander enumerates indications for local and general anesthesia, apparently giving preference to a combination of novocaine suprarenin anesthesia and nitrous oxide oxygen analgesia. The descriptions of the principal thoracoplastic operations, such as Wilms-Sauerbruch's and Brauer's operations, are carefully outlined and illustrated. The last chapter gives the results in detail of paravertebral thoraco-

plasty which gives rise to the hope that with the improvements in operative technic, preoperative and postoperative management, and especially in proper selection of cases for thoracoplastic surgery, surgery will ultimately be one of the most important factors in saving life in cases of pulmonary tuberculosis hitherto considered hopeless. By giving a bibliography of twenty pages, the author shows that besides his own valuable clinical studies he has devoted a great deal of time to reading the literature on the subject.

For this admirable work Dr. Alexander has received the Samuel D. Gross prize for surgery for 1925. He is to be coingratulated on this well deserved distinction and so is the American medical profession on having so valuable a guide in the surgery of pulmonary tuberculosis placed at its disposal. The book will aid physicians and surgeons in saving the lives of many tuberculous sufferers who may be restored to health and happiness and even to useful activities and an earning capacity. The printing, illustrations and binding are done with the usual excellence of the Lea & Febiger publications.

TUBERCULOSIS IN CHILDHOOD

La Mortalita Della Prima Infanzia Nelle Sue Relazioni con le Infezioni Pretubercolari e la Tubercolosi Soluzione Pratica e Definitiva di Questi Gravissimi Problemi. Par Dr. J. Ferran. Barcelona: Supplemento de *La Nipiologia,* Anno X, 1924. Pp. 47.

This is an interesting pamphlet of 47 pages giving a good summary of our present knowledge of tuberculosis in childhood, detailing the matter of tuberculous infection in early childhood and the relation a pretuberculous condition bears to the morbidity and mortality of tuberculosis in childhood. An entire chapter is devoted to the description of the methods of immunization, and twelve pages are devoted to statistical tables. The book is written in excellent Spanish and any tuberculosis worker familiar with the language will find it well worth while.

ARTIFICIAL SUNLIGHT

Artificial Sunlight and Its Therapeutic Uses. By Francis Howard Humphris, M.D. (Brux.), F.R.C.P. (Edin.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), L.M. (Rot., Dublin), D.M.R. & E. (Cantab.) New York: Oxford University Press. Second edition 1925. Pp. 194.

This book is essentially a consideration of ultraviolet light from a clinical viewpoint. Dr. Humphris does not go into the deep scientific side of it as much as he might have done to make the book more complete, but he presents the subject for a general clinician in about the best way that has been done so far. This second edition is better illustrated than the first one and the way the whole subject is handled makes it an extremely useful book for the practitioner.

The use of the carbon arc lamp in Europe is much more extensive than in the United States and the observations regarding this work are well worth understanding because the carbon arc is establishing a field of usefulness wherein the mercury arc lamp is not as good. Although both of these lamps generate ultraviolet light, the mercury arc lamp is so much more powerful that it hardly enters into the field of the carbon arc lamp.

NOSE, THROAT AND EAR

Diseases of the Nose, Throat and Ear. By William Lincoln Ballenger, M.D. Revised by Howard Charles Ballenger, M.D. Fifth Edition. Illustrated with 551 Engravings and thirty-two Plates. New York and Philadelphia: Lea and Febiger, 1925. Pp. i-1080.

The popularity of this classic in the literature of American otolaryngology is bound to be greatly enhanced by the appearance of this fifth edition, which, thanks to numerous additions of new matter and a thorough revision of the old texts, presents, both to the specialist and the general practitioner, a veritable encyclopedia of information on diseases of the ear, nose and throat. Its contents embody all our most recent advances in this special branch of medicine, such as (to take but a few instances) the last word on hay fever, hyperesthetic rhinitis and asthma, the medical and surgical aspects of labyrinthine conditions in the light of recent investigations, new operative procedures in ozena (Halle and Lautenschlager operations), etc. On the other hand a great deal of antiquated and obsolete matter had been thrown out, and every effort made by the editor to bring the book up to date—an attempt in which he seems to have succeeded admirably.

All in all the book can be unreservedly recommended as one of our best textbooks on otolaryngology. Its makeup as to paper, printing, etc., is of the high quality that we are accustomed to expect from the publishers.

THE EXTRA PHARMACOPŒIA

The Extra Pharmacopœia of Martindale and Westcott. Revised by W. Harrison Martindale, Ph.D., F.C.S., and W. Wynn Westcott, M.B., D.P.H. Eighteenth Edition, Vol. II. London: H. K. Lewis & Co., Ltd., 1925. Pp. 728.

The reviewer of this "externally" small book does not remember to have seen ever before one volume that contained so much information. Including the index (which is for volumes I and II) the book comprises 728 finely typed pages offering information on very many branches of chemical, laboratorial and practical medicine. Analytical tests, stains, and analyses are described, and among the many subjects discussed are radioactive substances and mineral waters. Incidentally the contents of many proprietary preparations are outlined.

It is regrettable that one of the authors, Dr. W. Harrison Martindale, did not live to see the success of his efforts in producing the eighteenth edition of this useful book.

HEALTH RULES

How to Live. By Irving Fisher and Eugene Lyman Fisk, M.D. Illustrated. New York and London: Funk & Wagnalls Company, 1925. Pp. 500.

The value of this useful book is definitely attested by the fact that this issue of 1925 is the eighteenth edition. Alterations from earlier editions include the omission of material which had become out of date, and the emphasis of the preventive and public health aspects of hygienic living. There is a section on quackery and its evils and dangers, and suggestions are offered for its suppression and the identifying of the professional quack and charlatan. The list of titles under which various quackeries are practised, which was compiled recently by the Department of Health of New York City, is quoted in this connec-

tion. There is a supplementary section on special subjects of particular interest at the present moment, such as the food question, the cardinal principles in weight regulation, hygiene of the brain and nervous system, the alcohol and tobacco problems, the common cold, focal infection, mortality and the chronic organic diseases, eugenics, etc.

The subject matter and treatment of the book as a whole, which is essentially popular, justifies its subtitle, Rules for Healthful Living Based on Modern Science.

HEALTH

Personal and Community Health. By Clair Elsmere Turner, Associate Professor of Hygiene in Tufts College Medical and Dental Schools. Illustrated. St. Louis: C. V. Mosby Company, 1925. Pp. 426.

The first chapter of this book causes immediate interest in the work of the author. The paragraphs of this chapter on the university viewpoint of health are especially well put, and the statement that "the number of really well people who are 'up and about' is relatively small" is correct. He also states that "faulty habits of living of the people at large is one of the most important factors working against the national health and efficiency."

These quotations show the author's belief in the necessity for a book of this type for students of all departments of learning, and in fact for all youth.

The chapters on foods and their adulteration, and on nutrition, as well as those on personal hygiene, from exercise to sleep, are excellent. The discussion of the prevention of disease, hereditary influences and immunity offers information that should be acquired by all, and especially by the youth of the nation. The chapters on community health measures should be studied by all citizens who are interested, or will be, in civic and state promotion of public health. Public health boards and health commissions include many laymen whose services will be more valuable after a study of this book.

After this sincere approval of the reviewer of the author's work, the latter should be willing to accept and consider one important criticism of a part of the book, however, for which he is not wholly responsible, namely, the chapter on hygiene of the mouth. This section on dental hygiene, written by Dr. William Rice, is excellent, except the part that discusses the toothbrush. Dr. Fones's teachings as to the method of using the toothbrush are copied, but like almost all similar discussions there is not a word as to the menace of the germ contaminated brush. The toothbrush is never sanitary. It cannot be cleaned, and must of necessity be a frequent carrier of infection. This danger is suggested by the following quotation from page 131: "The danger of infection of the soft tissues of the mouth by proper brushing is so slight as to be practically negligible." The author of this chapter also states, on the same page, that he "has found that a brush rinsed in water after using and then placed in a closed receptacle developed more bacteria than one which was rinsed in hot water and left in the air to dry." This positive acknowledgment that the toothbrush cannot be kept free from bacteria even "as the result of experiments" positively assumes that during any mouth or throat infection the toothbrush could contain and grow bacteria.

It is hardly necessary to suggest that the toothbrush could contain and perpetuate the germs that infect the tonsils, the germs that are associated with pyorrhea, with Vincent's disease, with diphtheria, and perhaps many other acute diseases that are acquired by way of the mouth. School toothbrush drills as now given, with the toothbrush used in the mouth and then carried home to be washed later, are an abomination. Substitutes for the toothbrush may at the present time be obtained, and doubtless new inventions will perfect them. The toothbrush used, imperfectly (of necessity) cleansed, hung in the dust and atmosphere of the bathroom, and again used on the following day, whether the individual has a cold, a sort throat or influenza, a canker sore, or a mouth ulceration, must go into innocuous desuetude.

The last paragraph of this chapter admits that there is "undoubted relationship between systemic infection and dental foci." Then the writer of the chapter says, "but to act upon the hypothesis that diseased teeth represent the sole cause of these systomic diseases and to advise wholesale removal of useful organs, is entirely unwarranted." This sentence is very unfair, as the writer of this review does not know that it has ever been asserted that "diseased teeth are the sole cause of these systemic diseases." The exact relationship of a diseased tooth to a systemic disease is practically of no importance whatsoever. *Every diseased tooth should be immediately removed as soon as discovered,* lest it be a factor in causing some future disease or diseased condition. We do not vaccinate after smallpox has developed; we do not give vaccines after typhoid fever has developed, or after diphtheria has developed, but we attempt to establish immunity *before* these diseases have occurred.

PEDIATRIC NURSING

Pediatric Nursing. A Textbook for Nurses. By Abraham Levison, B.S., M.D., Associate in Pediatrics, Northwestern University Medical School. Illustrated with twenty-seven Engravings and one Colored Plate. Philadelphia and New York: Lea & Febiger, 1925. Pp. 251.

This practical little book on pediatric nursing is divided into three parts. The first two parts are concerned with the anatomy, physiology and general care of infants in the home and the hospital, and the general methods of examination and treatment of children and also with concise descriptions of the diseases of infancy and childhood. The third portion, consisting of several chapters on the psychological and sociological phases of child nursing, is the most distinctive and valuable part of the book, as very few, if any, textbooks for nurses deal with this very important aspect of the subject. The subjects discussed include the art of child nursing, the expectant mother, the perplexed mother, the kind grandmother, the foreign mother and her child, hospital versus home treatment of the sick child, superstitious notions regarding contagious diseases, and the psychology of the sick child. These chapters contain some very sound commonsense and are worth the price of the book alone.

The subject material is well arranged and up to date and the book may well be recommended to every nurse, especially to one who specializes in the nursing of children, which is becoming very popular among the more well to do people.

Medicoliterary Notes.

One of the recent contestants for the record of the English Channel swim was a physician, Dr. G. B. Brewster, of Nesting, Shetland, who started from Folkstone Beach, swam twelve miles in three and a half hours, then had to give up seven and three quarter miles from shore because of the heavy seas.

* * *

An increasing number of women are entering the medical profession, and in the matter of examinations at least, they more than hold their own with men students. A somewhat surprising feature of women medical students is their preference of surgery to medicine.—*Medical Press and Circular.*

* * *

An editorial in a recent issue of the *Manchester Guardian Weekly* states that within the past six years the number of street accidents has nearly trebled itself in Great Britain, and one third of the victims are small children. For 1924, the casualty list of the streets was 3,651 killed and 94,584 injured. The National Safety First Association has had prepared under the title of *Safety First* a book for use by teachers and parents. It describes preventions and remedies for the various disasters that seem to await children and should be a very useful and helpful little volume. The publishers are Hodder & Stoughton.

* * *

The Offence, a play now running at a London Theatre, deals with a subject of special interest to the medical profession. Its chief purpose is to illustrate the theory of repression and its evil results, often after many years from the original cause and when the inciting circumstance has long been forgotten. Rumor has it that the play will be produced in New York next season.

* * *

What is the world's shortest letter? The records place it to the credit of Victor Hugo noted for his impatience and impetuosity. On the very evening of the day on which one of his new works was published he could not resist the temptation to inquire how the sales were going. So he wrote to his publisher:

"? Victor Hugo."

The publisher was equal to the occasion, for his reply was:

"!"—*New York Evening Post.*

* * *

Most of the streets of Vienna are paved with granite, and it has been found that many cases of silicosis with terminal tuberculosis have been caused by the dust arising from it. The city is experimenting with tar and oil as preventive measures, and it is asserted by the authorities that already, aside from a general improvement in the health of the people, the outlay for the tar and oil will be more than made up by the decrease in demands on public hospitals and physicians of charitable organizations who are paid by the state.

* * *

The people of New York are apparently very fond of buttermilk. There are a number of street stands where nothing else is sold, some of it fresh from the churn, so to speak, but most of them sell the synthetic variety, made from sweet milk by the addition of cultures. Restaurants, hotels, soda fountains and all sorts of quick lunch places report an enormously increased demand for this healthful beverage, especially within the past year.

* * *

The Bureau of Industrial Hygiene of New York State has recently issued a bulletin dealing with silicosis, with the hope that it will stimulate discussion of the subject by the medical profession and lead to an exchange of ideas and experience. This bulletin is distributed without charge to any physician upon request. Applications should be addressed to Dr. Leland F. Cofer, director, Bureau of Industrial Hygiene, 124 East Twenty-eighth Street, New York.

* * *

Lord Jim, one of Conrad's most popular novels, has been filmed in Los Angeles harbor recently. A strange and interesting group of sea craft was collected to give the proper atmosphere to the picture. There were sixteen vessels in all, ranging from an ordinary steamer to a Chinese junk. The steamer was built thirty-five years ago and is reported to have touched at every port on the Pacific coast. The old vessel had been allowed to sink in shallow water since it was so worn and out of date that it was considered useless, but it was raised and used in the picture, which represents the period in which it was built, furnished and equipped. Another interesting vessel used was the *Hackadada,* a mystery ship usually known as the *Adventurer.* The cargo is said usually to be secret, and the destination never certain. The ship is said to have sailed under five different flags within the past five years. Other craft were a three masted schooner which has already been used in the screen versions of *To Have and To Hold, Ebb Tide, Children of Jazz,* and *Peter Pan;* two American mine sweepers that were in the war, eight sampans from the Orient, and various other craft were used.

* * *

Survey of Hygienic Conditions in the Printing Trades is the title of a study by S. Kjaer made for the U. S. Department of Labor and issued as Bulletin No. 392 of the Bureau of Labor Statistics.

* * *

At a recent lecture at University College, Dublin, Dr. Porkory, a Berlin professor of philology, advanced the theory that the Irish are descendants of the Eskimos. He stated that in remote parts of Ireland and Scotland he had found types with Mongol features, including oblique eyes, straight black hair and thick lips. He believes that the first inhabitants of Ireland arrived there about 4,000 B. C., before which time the island was ice covered.

* * *

The issue for September 9th was the annual educational number of the *Medical Press and Circular.* The contents include a valuable list of the English universities, colleges, schools of medicine, intraacademical institutions, special hospitals, and postgraduate institutions that offer medical training, with an outline of the courses, conditions of study, and other pertinent information about each.

* * *

A book list for children has recently been compiled by certain libraries in the country, with the help of the children themselves, who were asked to recommend and criticize books. One fourteen year old boy, after reading *Evangeline,* declared that "it didn't seem possible that a girl would walk so many miles for her beau, when now a girl wouldn't walk a mile to see him."

* * *

Tuberculosis has been so rife lately in Hungary that a nationwide crusade has been undertaken for prevention. The Antituberculosis League, with Dr. Okolicsanyi Kuthy at the head, is managing the campaign. Registration of cases is to be the first step, then removal of infected persons to a camp in the mountains. The state is cooperating with local agents.

* * *

Robert Haven Schauffler was recently called back from a fishing trip in Maine to correct the proofs of his new anthology, *The Poetry Cure,* which his publishers, Dodd, Mead & Company, describe as a pocket medicine chest of verse, because that compiler has arranged the poems in it according to the moods that they are supposed to counteract, labeling some of them Anodynes for Sorrow, and others Stimulants for a Faint Heart, Pills to Purge Melancholy, etc. Just which prescription Mr. Schauffler took when his fishing trip companion wired that the three pounders were just beginning to rise we are not informed, but, as his pharmacopœia includes the best poetry from Chaucer to Millay, he was probably able to find something to ease his pain.—*N. Y. Times.*

* * *

Chicago is to have a Behavior Research Institute, allied with the existing Institute for Juvenile Research. A committee of fifty physicians and philanthropists has undertaken to raise the funds.

* * *

The proportion of childless marriages in civilized countries, according to Dr. E. Kehrer, director of the municipal gynecological clinic in Dresden, is from ten to fifteen per cent. The cause and cure of such a condition he declares to be one of the most important problems of modern eugenists.

Abstracts from Current Literature

THERAPY

Sodium Iodide in the Treatment of Infected Ulcers.—S. A. Pfannenstill (*British Medical Journal,* April 18, 1925) administers sodium iodide orally. This salt is very quickly absorbed into the blood and is so carried by the circulation to the ulcer. There it meets some second substance, applied locally, which can set free iodine from the compound salt. It is freed not only by chlorine and the hypochlorites (Dakin's and Carrel's solutions) but also by any strongly oxidizing substance such as ozone and hydrogen peroxide. Peroxide solution is preferred because it is the handiest and always constant in composition. Under these conditions iodine acts in the nascent state, thus increasing its already great bactericidal properties. Hydrogen peroxide, when in acid solution, frees iodine more easily and to a greater extent than in a neutral solution. The author therefore acidifies the peroxide solution with a small quantity of an acid, generally acetic acid, but boric acid may be used in the mouth as it avoids injury to the teeth.

In the case of an ulcer on the surface of the body or the limbs, an average dose of fifteen grains of sodium iodide is given two or three times daily. Larger doses may be given, sixty to ninety grains a day, the effect of the treatment then being greater; but this entails some risk of iodism. Immediately after the first dose of sodium iodide the local peroxide treatment is begun. A layer of cotton wool is kept continually soaked with the peroxide solution. The strength of the peroxide solution must be kept at one to three per cent., generally at one to one and a half per cent., because stronger solutions often irritate the sound skin around the ulcer. An addition of one quarter to one half per cent. acetic acid is quite sufficient for acidifying. After the last dose of sodium iodide has been given for the day the local treatment of the ulcer should be continued for at least three to four hours. Pockets should be packed loosely with gauze. The efficiency of the method depends upon there being an intimate and prolonged contact between fresh hydrogen peroxide and the infected surface to which sodium iodide is being carried through the bloodvessels. A surgical operation will sometimes make a fistula suitable for this treatment.

This method of treatment has proved very valuable in treating infectious conditions and ulcerations in the mouth and pharynx, such as mercury stomatitis, pyorrhea, gingivitis, and angina necrotica (Vincenti); also in tuberculous and lupoid ulcerations in the nose and throat, but with variable results.

Thyroid and Manganese Treatment in Various Diseases.—In a preliminary report, Herbert W. Nott (*British Medical Journal,* March 7, 1925) gives his results with the thyroid and manganese treatment in some cases due to toxemia or chronic infection, in many of which there was an element of thyroid inefficiency. The treatment consists in the administration of rectal injections of a solution of pure potassium permanganate, of various strengths, given at various intervals, according to the severity of the infection or the length of time it has existed. The standard solution used is one grain of permanganate to a pint and a half of sterile warm water. The dose of the thyroid is one grain, given twice daily on the average, but doses of one half to five or ten grains daily are in some cases desirable, with proportionate doses in children. Another method of giving potassium permanganate in an easily absorbable condition is by cachet. From one eighth to one half a grain of the pure powdered drug is enclosed in the smallest sized cachet. One is swallowed with half a pint of hot water on waking in the morning, when the stomach is empty, and four minutes later, another drink of hot water is taken. This is by no means as effectual as the injection method, but where continuous treatment is desired and when injections are not practicable, this method may be used with advantage.

A series of 227 cases of various types are reported, including acute infections (such as pneumococcal meningitis, cerebrospinal meningitis, acute and chronic bacillus coli infection); joint diseases (such as acute and chronic rheumatoid arthotis), heart diseases (such as cardiac asthma and angina pectoris); disorders of pregancy (such as morning sickness, eclampsia); disorders of metabolism (such as acute gout and diabetes mellitus); disorders of the digestive system (such as gastric ulcer and colitis); nervous diseases (such as infantile convulsions, chorea, and sciatica); pulmonary diseases (such as chronic bronchitis and asthma); skin diseases (such as malignancy, chronic seborrhea, pemphigus foliaceus, acne, acne rosacea and varicose ulcers); goitrous conditions (such as myxedema, parenchymatous goitre, and exophthalmic goitre); chronic mastitis, and some composite cases.

Iron in Nutrition.—I. Nutritional Anemia on Whole Milk Diets and the Utilization of Inorganic Iron in Hemoglobin Building. E. B. Hart, H. Steenbock, C. A. Elvehjem, and J. Waddell (*Journal of Biological Chemistry,* August, 1925) present data which support the original hypothesis of Abderhalden, that hemoglobin can be built from inorganic iron in the diet only when that diet is accompanied by certain organic structures, and further that milk is not only very low in iron, but that it is also low in the organic complex or complexes that make possible the building up of hemoglobin by the organism in the presence of inorganic iron. Rabbits fed on a whole milk diet well supplied with vitamine A develop a nutritional anemia. Inorganic iron added to the basal ration will not correct this anemia. Inorganic iron in the presence of fresh cabbage or an alcoholic extract of yellow corn meal will prevent or cure such an anemia. These extracts are free from iron.

Ultraviolet Light in General Practice.—T. Clyde McKenzie (*British Medical Journal,* May 9, 1925) has obtained good results with a quartz mercury vapor lamp of the atmospheric type in ulcers, eczema, alopecia areata, sycosis, lupus, burns, psoriasis, sciatica, local tuberculous conditions, chorea, rickets, and rheumatism. Ultraviolet light is by no means a panacea for all ailments, and in some of the diseases it was used simply in place of a more painful and cumbersome method. It often acts quicker than some of the older methods, allowing patients to go on with their work or return earlier to work than otherwise. It is especially recommended in industrial areas where sunlight is scarce and the patient is therefore more susceptible to ultraviolet action. The artificial sunlight bath appears to act on the general metabolism of the body—the appetite improves and the mental outlook brightens. This is particularly the case in industrial districts.

Use of Triple Distilled Water in the Treatment of Children.—Theodore Le Boutillier (*Archives of Pediatrics,* May, 1925) recalls that the intravenous use of distilled water has been employed for some time in massive doses, though small quantities, as now given, have produced speedy and spectacular results in many cases. With this treatment there is an average increase of the red cells, which lasts over a week, the white cells are not increased, but the hemoglobin in increased; the coagulation time of the blood is decreased, and the carbon dioxide content of the blood is changed remarkably.

The triple distillation of tap water removes all possible contamination or any poisons. The water should be freshly prepared and used within three of four days at the most to prevent absorption from the glass container.

Two methods of administration have been used. The first, and by far the best, is the intravenous method. The solution when injected should be as close to the body temperature as possible. Where a vein cannot be found it may be given intramuscularly, but this is distinctly painful for about fifteen minutes. The dose varies with the age and condition of the patient, from 0.5 to 1.5 c. c. intravenously, or 2.0 to 3.0 c. c. intramuscularly. In a chronic or subacute condition, one treatment a week will be sufficient, while in acute cases the treatment should be given at about two or three day intervals until a maximum result is obtained, at which time they should not be given more frequently than at weekly or two weekly intervals. A too large a dose will increase all the symptoms for which the patient is being treated.

Remarkably good results were obtained in cases of acidosis, some of them associated with cyclic vomiting, in pertussis, bronchial asthma, various forms of neuritis, scarlatinal rheumatism, urticaria and eczemas, and angioneurotic edema.

A Study of Insulin Action.—Edward C. Mason and C. W. Matthew (*Journal of Laboratory and Clinical Medicine,* July, 1925,) studied the rôle of the nerve mechanism in insulin action, by means of stimulating or paralyzing portions of the autonomic and central nervous system of rabbits and dogs, and following such procedures with insulin administration and blood sugar determinations. Insulin apparently acts independently of the central nervous system, the sympathetic nervous system, and the parasympathetic nervous system. The blood sugar was lowered by insulin after the following procedures: the destruction of the central nervous system; the administration of atropine in doses sufficiently great to paralyze the parasympathetic endings; and the administration of nicotine and lobeline in doses which stimulate and paralyze the sympathetic ganglia. One animal which was pithed, brain and cord, and which also received atropine and nicotine, showed a marked increase in blood sugar following the administration of excessive doses of insulin. Small doses of nicotine which stimulate the sympathetic system do not counteract the blood sugar lowering produced by insulin.

Treatment of Angina Pectoris.—Joseph T. Wearn (*Medical Clinics of North America,* March, 1925) states that the value of digitalis and nitrites is too well known for comment. The value of theobromine, however, is not so generally understood. Its use is, however, based upon sound pharmacology. One of the striking effects of theobromine is dilatation of the coronary arteries. Theobromine will give relief at times when nitrites fail, and if given daily may reduce the number of anginal attacks appreciably. Of much greater importance, however, than isolated anginal attacks is the whole problem of treatment. For the individual attack it is generally accepted that drugs are indispensable and almost invariably give immediate relief, but depending upon drug therapy alone is as unwise as depending upon rest alone. A rational combination of rest in the cases in which exhaustion plays a rôle and in instances of the very early signs of heart failure should be borne especially in mind. The importance of these therapeutic procedures is great, and when they are employed together with a careful and wise regulation of the patient's life and activities good results may be expected.

The Use of Iodine in Goitre.—Frank H. Lahey (*Boston Medical and Surgical Journal,* September 10, 1925) stresses the point that Lugol's solution was not intended as and is not a cure for exophthalmic goitre, that it is solely a method of preparing patients for operative procedures so that they will endure them more safely and that a lessened number of steps may be employed. He urges that Lugol's solution be not administered to patients suspected of thyroidism until the diagnosis has been proved. He also urges that, if operation is to be undertaken upon a patient with exophthalmic goitre, he be sent to the surgeon without having had Lugol's solution. This for two reasons; one, in order that the Lugol's solution may be given under the observation of the person who is to do the operation, and, two, that he may be aware of the condition of the patient before the drug is given and of the benefit obtained by its use, as this aids materially in determining whether a divided stage operation is needed or not. While Lugol's solution is of great value in eliminating the necessity of multiple stage procedures, it must not for a moment be considered that every patient who has been prepared with it can safely withstand a subtotal thyroidectomy in one stage.

Treatment of Neuritis by Electrolysis.—W. Black Jones (*British Medical Journal,* January 17, 1925) reports that electrolysis gives good promise of relief in cases of neuritis where the lesion is of the interstitial type, due to inflammation of the nerve sheath.

The apparatus consists of a pantostat, or similar instrument, with two electrodes, one being a large pad, which is applied to the arm or leg, and a smaller pad or button. An insulated needle, with a platinum point, is fixed in a holder, and is used for the actual treatment.

For diagnosis, the pads are soaked in a warm salt solution, and the larger is applied to some neutral part of the body, such as the wrist; both are connected with the terminals of the induction coil. The current used should be so weak that when the small pad is applied to the normal skin it is hardly felt; when it approaches the site of the inflamed nerve a distinct pain, or series of shocks is felt. This area is marked with a pencil. Should no tender point be found it may be concluded that neuritis is not present.

For treatment the skin is swabbed with iodine, and a few drops of local anesthetic are injected under the epidermis. After a few minutes the platinum needle, having been connected with the negative pole of the constant current, is inserted into the skin and pushed down upon the nerve. The large pad is connected with the positive terminal. If the spot is very tender a current of one milliampere or less is applied, but sometimes from three to five milliamperes may be used. The current is allowed to flow for ten minutes; it is then gradually turned off and the needle is withdrawn. Only one spot should be treated on the same day, and a day's interval is advisable before the next treatment. It is important to note that, in cases of multiple spots, complete relief is not obtained until all spots have been treated. It is probable that the electrolysis converts the sodium chloride of the tissues into sodium hydrate, and this has a caustic effect on the exudation.

Treatment of Tetanus.—Carroll Smith and W. E. Leighton (*American Journal of the Medical Sciences,* December, 1924) say that the rational treatment of tetanus should be carried out as follows:

1. Prophylactic antitoxin, subcutaneously in all suspicious wounds, repeated again after ten days, especially if suppuration is present, or if an operation is to be performed.
2. Antitetanic serum should be given during an attack of tetanus. Intravenous administration may be satisfactory. Intraspinal serum should be employed in severe cases or where improvement is not satisfactory.
3. Spasms should be controlled by the subcutaneous injection of magnesium sulphate. In urgent conditions or when the subcutaneous method fails the intraspinal or even the intravenous route should be used. Morphine sulphate, in addition to magesium sulphate, may aid at times. Careful personal observation is necessary in order to judge the dose and method of administration of magnesium sulphate.
4. The wound of infection should be opened and cleaned, and air should be allowed to reach it. Tincture of iodine should be used locally. Serum should be injected at the site of the wound to block the progress of the toxin.
5. An intramuscular or subcutaneous injection of serum should be given on the eighth or ninth day after the beginning of the treatment, in order to keep up the prophylaxis.
6. Fluids and nourishment should be supplied, and careful nursing is essential.

A Study of the Efficacy of Certain Antidotes in the Treatment of Acute Bichloride of Mercury Poisoning.—W. H. Ziegler (*Journal of Laboratory and Clinical Medicine,* January, 1925) used dogs and rabbits in this work, in which bichloride of mercury and the antidote, having been dissolved in sterile normal saline solution, were injected into a branch of the vena saphena parva on the lateral face of the leg. The author says that the minimum lethal oral or intravenous dose of bichloride of mercury for the dog cannot be based upon the weight of the animal. The lethal oral dose of bichloride of mercury for the dog is two hundred mg. (about three gr.) and the minimum lethal intravenous dose forty mg. Calcium and sodium sulphides, dissolved in water and administered by mouth grain for grain, are effective antidotes for acute bichloride of mercury poisoning, if administered before gastrointestinal symptoms have occurred. When a total dose of forty mg. of bichloride of mercury is injected intravenously, calcium sulphide, sodium sulphide or sodium iodide is of no value as an antidote administered either orally or intravenously. Mucilage of acacia will prevent the corrosive action of bichloride of mercury and delay the absorption. In considering the treatment Ziegler states that if the patient is seen immediately after taking the bichloride of mercury, washing out of the stomach with a 1-1000 unfiltered solution of calcium sulphide is the best treatment, followed by the administration of about 300 c. c. of mucilage of acacia, U. S. P. If vomiting has already occurred, this same treatment should be used, but if other gastrointestinal symptoms are present, calcium sulphide is contraindicated. The stomach should be washed out carefully and quantities of mucilage of acacia given both by mouth and by high colonic injection. A mild cathartic should be given. If anuria is present, efforts should be made to restore this function. A mixture of acetate of potash, caffeine citrate and infusion of digitalis should be given every four hours for several days. The author does not believe that a satisfactory antidote has been found which when injected intravenously will change the bichloride into a less corrosive salt.

Iodine Treatment of Goitre.—Eugen Bircher (*Klinische Wochenschrift,* April 16, 1925) advances the following basic principles for the future nonoperative treatment of goitre: 1. The careful use of iodine. 2. The injurious byeffects of iodine must be minimized or prevented by the use of counteracting remedies, such as calcium and quinine, and possibly phosphorus. 3. In the large group of individuals who show an idiosyncrasy to iodine, the iodine must be entirely replaced by other remedies, among which silica and phosphorus seem to be the most promising; possibly other halogens (bromine) or the metalloids (arsenic and mercury) may also be of use. 4. In general, a varying combination therapy with or without iodine, with quinine and its derivatives, silica and phosphorus, is advisable in goitre, each case of which must be judged individually.

Effect of Potassium Oxalate on Blood Sugar Determinations.—Henry J. John (*Journal of Laboratory and Clincal Medicine,* September, 1925) found that the quantity of potassium oxalate put in tubes for blood sugar determinations, to prevent clotting of the blood, bears a definite relation to the blood sugar determination. As the amount of oxalate is increased, the blood sugar content figure is decreased in both diabetic and nondiabetic bloods. Since the variation in the blood sugar estimation is small when the amount of oxalate varies between fifteen and thirty mg., for routine work this amount is suggested.

The Ketogenic Diet in the Treatment of Epilepsy.—M. G. Peterman (*Medical Clinics of North America,* January, 1925) starts the ketogenic diet abruptly. The patient is given a diet of carbohydrate 50 gm., protein 25 gm., and fat 70 gm. for one or two days. He is then given carbohydrate 40 gm., protein 20 gm., and fat 80 gm. Following this, on the fourth or fifth day, the diet is modified to carbohydrate 20 gm., protein 20 to 30 gm., and fat 92 gm. If there has been no nausea or emesis, the patient is then put on his full diet prescription, which consists of 10 to 15 gm. of carbohydrate a day, 1 gm. of protein for each kilogram of body weight, and fat for the remaining calories. (Excessively obese patients require special consideration). The total caloric intake should not exceed the actual metabolic requirements. The caloric requirement is easily calculated from Wilder's chart. Thirty to fifty per cent. is added to the basal metabolic requirement. Provision is made for the vitamines and salt.

Perineural Injections of Antipyrin.—F. Högler (*Wiener klinische Wochenschrift,* January 15, 1925) says he has obtained some good results in acute cases of sciatica with perineural injections of antipyrine. The technic, if strictly adhered to, is devoid of all complications. It is described as follows:

The solution is made by adding three to five grams of antipyrin to ten c. c. of distilled water and one c. c. of a one per cent. solution of novocaine is added. This solution is injected at one time perineurally at the most tender points over the sciatic nerve. The site of injection may be anesthetized with a drop of carbolic acid. The injection is made with a not too thin needle, ten cm. long, after palpating for the nerve. The piercing of the nerve is announced by a lightninglike pain in the toes. When this happens one is sure that no harm can result from the injection, and the needle should then be slightly withdrawn, and the injection made. This form of treatment often helps when nothing else will.

Antimicrobic Properties of Various River and Sea Waters.—F. Arloing, Sempé and Chavanne (*Bulletin de l' Académie de médecine,* February 17, 1925) report investigations on the antimicrobic power of various samples of river and sea water on bacteria of the intestinal group. Striking qualitative differences in the antibacterial properties of different rivers were noted. Thus, the antityphoid property was predominant in the waters of the Rhône and Isère; the antiparatyphoid A property in those of the Isère and the region of Grenoble, and the anti-Shiga property in water from the Bay of Havre. The anticolon bacillus property proved the most widespread, and was met with in particular in somewhat rapidly flowing streams or the most highly polluted waters such as those of the Saône, Seine and port of Havre. The water of a stream was generally more strongly antimicrobic when obtained below a city than above it. Rises of the stream level sometimes increased or distributed the antimicrobic property. The latter shows marked diminution and a tendency to disappear in water filtered through a porcelain filter and kept in darkness in a sealed tube for a month. That time weakens the bacteriophage is well known. Water from springs shows less bactericidal power than river waters polluted through having coursed for some distance in the open. Melted clean snow from the col de Porte, at an elevation of 1,350 metres, showed very intense lysis of the paratyphoid A; intense, of the typhoid bacillus; strong, of the Shiga, and none, of the colon bacillus and paratyphoid B. The writers are inclined to ascribe the lytic action of waters to the presence of a polyvalent bacteriophage rather than to nonspecific causes. In favor of the bacteriophage is the fact that dilution does not present lysis, and that lysis is enhanced under the same conditions as have a like effect on d'Herelle's organism. The variation in action on different bacterial species, the weakening with lapse of time, etc., also support this view.

Psicaine: An Artificial Cocaine.—E. Watson-Williams (*British Medical Journal,* January 3, 1925) states that psicaine is the acid tartrate of an artificial isomer of cocaine. It is soluble in water, giving a definitely acid solution. The solution is not harmed by brief boiling. It requires the addition of salicylic acid to prevent the growth of moulds. Used in the nose, seven per cent. psicaine solution gives anesthesia identical with that produced by five per cent. cocaine hydrochloride solution. The same "shrinkage" as is seen with cocaine is found in using psicaine. The experimental toxicity of psicaine in five per cent. solution is three quarters that of cocaine hydrochloride; the toxicity of the new alkaloid is therefore identical with that of cocaine.

It is probable that excitement, fainting, etc., will not be so readily produced by psicaine as by cocaine; it may therefore be useful in susceptible persons. For the same reason psicaine should not be used except by those well accustomed to use cocaine; the dose of psicaine should not exceed that found safe with cocaine. Psicaine is, therefore, a "dangerous drug."

A Clinical Study of Quinidin Therapy.—Herman H. Riecker (*American Journal of the Medical Sciences,* August, 1925) says that the use of quinidin sulphate is justified and seems indicated in all cases of auricular fibrillation, except in those in which there are signs of recent embolism, marked decompensation of the heart or early appearance of the symptoms of cinchonism. Both the temporary and permanent conversion of the fibrillation to a normal sinus rhythm by the drug seems to be favorably influenced by the presence of a delayed conduction time at the auriculoventricular junction. The careful management of cases with regard to exercise, mental excitement and fever during quinidin administration greatly facilitates the favorable action of the drug. The administration of quinidin is most effectual when given continuously through the day and night as suggested by the work of Lewis. The use of digitalis to maintain the rhythm after its conversion seems to be even more important than that of quinidin in chronic auricular fibrillation.

Therapeutic Value of Coramine.—K. Guth (*Therapeutic Gazette,* September 15, 1925) states that coramine is a preparation the action of which is in every respect equal to that of camphor. Its advantage seems to lie in the fact that it is soluble in water.

Clinical Value of Ephedrin.—T. Grier Miller (*American Journal of the Medical Sciences,* August, 1925) says that ephedrin has general physiological effects in man similar to those produced by epinephrin. It has, however, distinct practical advantages over epinephrin because of its more prolonged action and the fact that it can be administered effectively by mouth.

In doses of fifty to one hundred and twenty-five mg., given orally or subcutaneously, ephedrin sulphate usually raises the systolic and diastolic blood pressure and decreases the pulse rate for a period of several hours. It also stimulates the heart action and has a tendency to increase the output of urine. It sometimes increases the basal metabolism.

Its administration caused temporary improvement in two cases of Addison's disease, gave relief in the paroxysmal attacks of certain cases of asthma, relieved the subjective sensations in a case of urticaria, caused a disappearance of urticarial lesions in a case of serum disease, and produced marked temporary improvement in a case of circulatory collapse and steady and continuous improvement in a case of circulatory failure incident to myocardial disease and the evacuation of an overfilled urinary bladder.

In a single case of complete heart block it produced an increase in both the auricular and the ventricular rates and caused alterations in the character of the electrocardiographic tracings.

Locally applied to the nasal mucous membrane, ephedrin causes prompt contraction which persists for more than three hours and has no local irritant effect.

It is believed that the widest range of usefulness of ephedrin will be found in the treatment of asthma and of acute circulatory depression, and in the management of certain congestive nasal conditions.

Oral Administration of Large Quantities of Glucose.—T. Izod Bennett and E. C. Dodds (*Lancet,* February 28, 1925) found that large quantities of glucose can be administered in palatable form and at a low cost. Its exact chemical composition is difficult to determine, but it is shown to contain arsenic in negligible traces and to have a caloric value of about one thousand large calories a pound. Normal persons can assimilate quantities of two hundred to five hundred grams in one does, without passing more than a trace of sugar in the urine. The main effects on subjects who took five hundred grams in this manner were: 1, diuresis; 2, a rise in blood pressure not greater than what occurs after a normal meal; 3, no change in the respiratory quotient; 4, a marked hypnotic effect in two cases. Large quantities of sugar taken in this manner appear to be detained and diluted in the stomach. There is also evidence of a dilution of the blood.

Large quantities of glucose have been added to the diet as a therapeutic measure in many clinical cases, particularly in acute infections and in cases with marked undernutrition. Distinct benefit appears to have resulted and no ill effects have been observed.

Ethylene.—L. F. Sise (*Boston Medical and Surgical Journal,* February 12, 1925) gives a description of the physical and physiological properties of ethylene, which are first brought to notice in 1922 ,together with its uses, the clinical results produced, and the precautions to be observed. It is an anesthetic gas dispensed compressed in steel cylinders. Sise says that ethylene is the purest anesthetic which we have today in that for a given depth of anesthesia it produces less effect on the body than any other known anesthetic. It can be used with a considerably higher mixture of oxygen than can nitrous oxide and it gives better relaxation. But it does not give relaxation which can compare with that of ether and therefore it cannot replace ether for abdominal surgery with subjects who are in good condition. Its one serious drawback is its inflammability; and this should be carefully guarded against. It is preeminently the anesthetic for the handicapped and "bad risks" patients. It is undoubtedly the best general anesthetic which we know today for such patients.

The administration of ethylene is very similar to that of nitrous oxide and is comparatively easy for those who are already skilled in the use of the earlier gas. The main points to be emphasized are:

1. The percentage of oxygen may be higher, usually about fifty per cent. or more higher than with nitrous oxide. The color of these patients is sometimes spoken of as an unnatural pink, suggesting a combination with hemoglobin, though no such combination has been shown to exist.

2. The patient may be run somewhat lighter. This is due to the fact that its analgesic properties are decidedly greater than are those of nitrous oxide. Thus, under ethylene a patient may be pink and have an active lid reflex and still make no movement at the beginning of operation, as so often happens under nitrous oxide even though he is slightly cyanosed and snoring.

3. More care should be used not to overdose the patient, especially during induction. This was a personal impression which the author received from clinical experience, and which he has not seen mentioned by other observers, although Gwathmey does say that this gas must not be pushed, and several observers have mentioned pallor under its use.

4. Eye signs closely parallel those under nitrous oxide.

5. The breathing is somewhat slower and less vigorous.

6. Ethylene freezes in the valves of the apparatus much more readily than the present anhydrous nitrous oxide, so that some sort of heating device is usually necessary. This must *not* be a lamp, but may be an electric heater or hot water bag, because it is inflammable.

Treatment of Varicose Veins of the Leg by Injections.—John Dunbar (*British Medical Journal,* January 3, 1925) reports his results in thirty cases of varicose veins of the leg treated by injecting these veins with sodium salicylate. The method is the following:

The susceptibility of the patient is first tested by injecting about one c.c. of twenty per cent. solution into the veins. If there is no reaction next day a stronger solution is used, but it is recommended not to go above forty per cent. Several sections can be injected at the same time, but the total dose of sodium salicylate should not exceed three gm. No constricting band is used. The patient, as a rule, complains of a severe pain coming on immediately after the injection and lasting about one minute. If a cure does not result, the treatment can be repeated. About a week afterward, one or two findings indicate if a cure is going to be effected: 1, a hard mass is felt in the vein at the seat of injection; 2, in addition, the thrombosis extends down the vein in some cases. In no case was extension up the vein noticed. Later, the vein becomes replaced by a fibrous cord.

On account of the severe pain after the use of sodium salicylate, the author tried mercury perchloride (1 in 500 solution). There is less pain, less swelling of the vein, and the results are as good. Under no circumstances should an inflamed vein be injected. The results from the injection treatment are not claimed to be better than those obtained with operation, or that the liability of the return of the varicose condition is less (in fact the percentage of recurrences might be expected to be higher), but the circulation in the legs is certainly improved, and consequently the strength of the lower extremities is increased without incapacitating the patient in any way.

Peptone and Serum Peptone in Asthma.—A. G. Auld (*British Medical Journal,* March 7, 1925) states that peptone acts by changing or desensitizing the interior of the body, so that the disease has little chance of attacking. Some persons are better for this purpose than others in whom the antianaphylactic reaction is defective or wanting. Those who have had much disease, and especially suppurative lesions, are resistant. The peptone is usually given intravenously and slowly, and when the patient is as free from asthma as possible. The intravenous injection is absolutely safe, even in the youngest child. In some cases, the peptone may be given intramuscularly in doses of 7.5 per cent. especially in children and old weak people. When this does not act satisfactorily, however, the intravenous use of the five per cent. solution should be made.

Intravenously, five minims of the five per cent. solution is an excellent beginning, continued twice a week by an increase each time of three minims, until twenty-six minims are reached. Continue this last dose for two more doses, which makes the tenth dose. By this time it will be found that there are three classes of cases: 1, the patient may feel surprisingly well; 2, he may be much improved; 3, he is improved only a little. In the first class it is only necessary to increase the dose by about four minims for two more doses, and then giving weekly twenty-five, twenty, fifteen, and ten minims, when the treatment is finished. In the others, if the patient is standing the peptone well, the dose is increased to two c. c., then two point five c. c., or even to three c. c.; then reduce weekly, by about ten minims to thirty-three, twenty-three, and thirteen minims. If an attack of asthma intervenes, reduce the dose considerably, say to twenty-five minims. Continue this for two or three weeks, then reduce weekly to fifteen and ten minims. When the patient is weak, the dose must be kept low.

When bronchitis is present a vaccine may be considered. In this case first give peptone for about two weeks, which will render the patient tolerant to vaccine, to which asthmatics are often very sensitive.

When human blood is incubated with peptone in vitro a change occurs in the serum and the peptone which renders the mixture highly suitable for the treatment of asthma. It has been found that two or three c. c., of the twenty per cent. mixture does not produce reactions in man as a rule. The dose is as follows, when the patient is as clear of asthma as he can be: 0.5 c. c., 1 c. c., 1.5 c. c., 2.0 c. c., 2.5 c. c. 3.0 c. c., given twice a week intravenously. If the higher doses produce any reaction, reduce it slightly. Then give 2.5 or 3.0 c. c. for two weeks, and 1.5 c. c. one week, and 1.0 c.c. the next week. The latter doses are given once a week. This is, of course, only a general treatment and great variations may be required.

NEUROPSYCHIATRY

Amaurotic Family Idiocy.—J. Epstein (*Archives of Pediatrics,* April, 1925) states that amaurotic family idiocy is a disease of an indefinite etiology, a definite pathology, a uniform clinical course and a fatal prognosis. There is no definite evidence of an hereditary taint, a congenital abnormality, or a latent infection that would throw any light on this destructive disease. That it is found exclusively among Jewish children is a biological enigma. The onset of the disease and the subsequent events in the life and death of the child indicate a degenerative pathogenesis of the central nervous system, especially of the nerve cells and ganglia. While it manfests itself at the age of about six months, the exact time the illness begins is quite unknown. The symptoms are those of a general retrogression with a gradual and constant disintegration of body and mind. The age of onset, the peculiar facial expression of idiocy and blindness, the hyperirritability and the spasticity, and the cherry red spots make the diagnosis. The disease is chronic and relentless in its course, leading to a fatal termination.

Treatment of General Paralysis by Malaria.—T. Wishart Davidson (*British Medical Journal,* March 7, 1925) states that the malaria treatment of general paralysis is justifiable and hopeful, provided the patients are in fair physical health. The earlier the case the better the prognosis. The treatment is contraindicated when the patient is likely to have a fatty heart or where there is poor physical health. The administration of strychnine, with digitalin or strophanthine to steady the heart, is advisable and helpful, especially during the later pyrexial attacks. Relapses of malaria do occur, but practically only in mosquito infected cases. Compared with the infection by the inoculation of trophozoites, it would appear that infection by the sporozoites from mosquito produces a parasite which readily becomes resistant to the immune body, and thus relapses frequently occur. A previous attack of malaria would appear to induce partial immunity; although scanty parasites appear in the peripheral blood, there is no rise of temperature.

The malarial treatment was carried out in fifty-three cases of general paralysis. Complete remissions occurred in seven cases; nine patients improved mentally and physically, and seventeen showed slight mental improvement with a considerably improved physical condition.

Encephalitis Lethargica.—C. M. Hinds Howell (*British Medical Journal,* March 7, 1925) states that there is unfortunately no specific treatment that has proved its value for encephalitis lethargica. He is convinced of the importance of recognizing the early ambulatory type of the disease and putting the patient to bed. Treatment on general lines must be carried out in so far as diet and regulation of the bowels are concerned. Most of the patients suffer from obstinate constipation. A gargle of potassium permanganate may well be used by the patient, if he is in a condition to do so—and by those in contact with him.

With regard to any special therapeutic measures, it is safe to say that none has so far offered convincing evidence of success. Hexamine has had an extended trial by the mouth, hypodermically, and intravenously, but the results have been disappointing. In some cases serum, either from the patient, or simple horse serum, and in some cases antimeningococcal serum, has been used apparently with advantage. Repeated lumbar puncture has been recommended although it is difficult to see on what logical grounds. The author has, however, seen an improvement in the depth of the lethargy follow a lumbar puncture. Insomnia, delirium, or excitement can be dealt with on ordinary lines. The residual symptoms or sequelæ are extraordinarily resistant to every therapeutic measure.

The Permeability of Meninges to Uranin as a Method in the Diagnosis of Meningitis.—Otto Jervell (*British Medical Journal,* January 31, 1925) in a preliminary communication, concludes that uranin in doses of 0.03 gram to the kilo of body weight does not enter the cerebrospinal fluid, or does so only in small quantities if the meninges are not infected. In meningitis the coloring matter enters the fluid in easily demonstrable quantities. If, therefore, by lumbar puncture threee hours after uranin has been given in the doses stated, the spinal fluid shows a distinct greenish fluorescence, we can with great probability diagnose meningitis without making other investigations of the spinal fluid. If the spinal fluid shows no fluorescence, meningitis can with certainty be excluded.

It is not possible to decide what form of meningitis, if any, is present. The passing of the coloring matter into the spinal fluid merely indicates the greater or lesser permeability of the meninges. In meningitis comitans, circumscripta, etc., the uranin does not enter the fluid, or does so in relatively small quantities, even when the pleocytosis is present. Opinions differ as to whether it is correct to designate these conditions meningitis, but this is doubtless chiefly a dispute about words.

Possibility of Restoring Movement to a Paralyzed Vocal Cord by Nerve Anastomosis.—Lionel Colledge (*British Medical Journal,* March 21, 1925) conducted an experimental inquiry on the effects of an anastomosis of the recurrent laryngeal nerve with other nerves.

Although a nervous connection may be reëstablished by a recurrent laryngeal vagus anastomosis, it is quite useless to expect return of spontaneous movement in the corresponding vocal cord.

The results of experiments with the descendens noni show that, as in an anastomosis with the vagus, the muscles controlling the movements of the vocal cord become innervated, but no movement occurs in the cord because the appropriate impulse does not pass along this route.

Experiments on anastomosis with the phrenic nerve, however, is capable of reproducing the normal movements of the vocal cords in tranquil respiration. The movement of adduction, induced by partial asphyxiation reappears before that of the abduction, which corresponds to the weaker extensor movement in the limbs. It is shown from these experiments that spontaneous respiratory movements can be restored to the vocal cord by an anastomosis between the recurrent laryngeal and the phrenic nerves. The entire trunk of the phrenic is not necessary, and probably it will be sufficient to use half the trunk, as in a lateral anastomosis, or one of the roots arising from the cervical nerves.

Pathogenesis of Various Forms of Tetany.—Otto Teznor (*Monatsschrift für Kinderheilkunde.* December 1924) found that, administered to the same patient, calcium lactate acts just as favorably upon the tetanic symptoms as ammonium chloride; the action of the monacidosic calcium lactate shows that every administration of calcium leads to the increase in the number of the calcium ions even with a constant acidity of the blood, even if the action of the nonionized portion of the blood calcium is not recognized It is impossible to determine a definite difference between the hydrogen ion concentration and the total acidity of the urine in healthy and tetanic children brought up on cow's milk. In practice, ammonium chloride is preferable to calcium lactate because of the more rapid and energetic action.

If a hyperventilation tetany is produced experimentally in a patient, and if in a second experiment an infusion of a four per cent. solution of bicarbonate is given, the latter produces no tetany if the produced alkalosis is just as high as it is in the respiratory tetany. This shows that other factors besides the alkalosis are responsible for the nervous irritability. It is possible that the hypertonia produced in the blood by the infusion acts in an inhibitory way and thus prevents the occurrence of the tetany.

The Femoral Reflex, a New Symptom of Tetany.—Géza Petényi (*Monatsschrift für Kinderheilkunde,* September, 1924) describes a new symptom of tetany in children, which he calls the femoral reflex. If the anterior surface of the thigh between the upper and middle third is tapped with the percussion hammer, the quadriceps muscle contracts and the leg makes a jerking movement forward, just as in the elicitation of the patellar reflex. The latter is obtained by tapping on the lower part of the tendon. If the reflexes are exaggerated, it is often possible to elicit it by tapping over the part of the tendon lying over the patella. It can readily be shown that the femoral reflex has nothing in common with the patellar reflex.

Among thirty-seven cases of tetany the femoral reflex was found to be present in sixty-eight per cent of the cases. It is of value, not only because it is demonstrable in a large number of cases, but also because it is simple and does not produce any pain. It has also occasionally been found to be the decisive factor in the diagnosis. This phenomenon occurred only three times in a series of 240 cases of children, some of which were healthy and some affected by other diseases. This reflex has been observed only during the first three years of life, and never in older children or in adults. The oldest child in which it was observed was two and a half years of age.

The Histopathology of Postencephalitic Parkinson's Syndrome.—Leslie B. Hohman (*Bulletin of the Johns Hopkins Hospital,* June 1925) in a case of postencephalitic Parkinson's syndrome, found the histological picture, except for the changes due to fever and poor fixation, to consist in evidence of moderate cell degeneration in the corpus striatum with an intact globus pallidus; a severe and profound destruction of the substantia nigra; focal areas of loss in the cerebral cortex in both cells and fibres; evidence of definite but very slight inflammatory changes; and very little glia increase. In summarizing eleven cases previously reported, to which the present one is added, Hohman states that the lesions in this condition are an essentially chronic degenerative parenchymatous process with constant persistent evidences of inflammatory reaction; widespread distribution of the lesions in every part of the central nervous system; and the region of maximal and constant involvement is the substantia nigra.

Injuries to the Musculospiral Nerve.—W. R. and Andrew R. MacAusland (*American Journal of the Medical Sciences,* January, 1925) say that the nerve may be injured in three ways: The nerve trunk may be crushed without damage to the sheath; the nerve may be completely divided; power may be lost through the involvement of the nerve in scar tissue or callus.

Early recognition and treatment of nerve injuries in connection with fractures and severe traumatisms is very important. We may expect a perfect result in cases of immediate suture of the nerve. While intervention in cases of old standing has given good results, it is the general opinion that the chances of success are lessened after the elapse of a long period of paralysis.

Simple freeing of the nerve is very often the only procedure necessary to relieve the condition. In cases of complete division of the nerve or in cases in which there is need to excise a portion of it because of a fibrous formation, nerve suture has been found the most satisfactory procedure for the approximation of the nerve ends. If the nerve suture does not relieve the condition, or if the case is not reparable by the various methods of manual stretching, neurotomy or nerve grafting, then tendon transplantation gives satisfactory results.

After severance of a nerve, healing begins spontaneously. In cases of nerve suture function develops in the same manner as in spontaneous healing. After secondary suture sensibility returns early. Muscle control usually appears in the course of two to four months and is complete in from six to nine months.

Tumors of the Cerebrum.—H. S. Souttar (*British Medical Journal,* March 21, 1925) shows that those tumors of the cerebrum which are accessible to surgery give rise in many instances to symptoms characteristic of their locality, though when the case is actually seen these are only too often masked by those of general intracranial pressure.

The commonest tumor of the cerebrum is a glioma and its removal is impossible. The relief which may be obtained by decompression is, however, sometimes very considerable. Although a glioma cannot be removed it may degenerate in the centre and become cystic, and in such a case it is sometimes possible by aspiration of the cyst to give considerable relief to the patient. If the cyst is at all superficial and can be treated with formalin the relief may extend over a considerable period; in some of these cases the introduction of radium has given good results. In such cases a decompression not only relieves the pressure but it enables the cyst to be aspirated with facility.

The only removable tumors which are at all common in the region of the cerebral hemispheres are the endotheliomata. These arise from the inner surface of the dura, probably from the lacunae of the anterior longitudinal sinus. Sometimes they are firm, rounded, fibrous tumors, often, however, with central degeneration; sometimes they are soft and diffluent. They may have a pedicle or they may be sessile on the inner surface of the dura. The bone over them is very vascular, and they have a curious power of stimulating its growth, so that external bony tumors may appear on the skull. They may, indeed, invade the bone, with which they thus become indissolubly connected, but in no circumstances do they invade the brain; they press into its substance, and their removal may at first leave a large cavity, but in a few moments the brain returns to its normal position and the cavity is entirely obliterated. Theoretically these tumors should be completely removable and should never recur, but this result is not always obtainable. In the soft type the tumor may break up so far that there can be no certainty of its complete removal, and in the sessile variety its connections with the superior longitudinal sinus may be so complete that only a resection of the sinus, with the grave risks which that involves, could ensure total ablation. Although a complete cure is effected by surgical interference in only a limited number of cases, there are many in which considerable relief is secured. The most important factors in success are early diagnosis and precise localization.

Peroxidase Reaction in Epidemic Encephalitis.—Sato and Yoshimatsu (*American Journal of Diseases of Children,* March, 1925) render their report on a characteristic feature of the blood picture of epidemic encephalitis which they believe will prove extremely valuable in diagnosis and prognosis. They produce evidence that the peroxidase test (copper method) of Sato and Sekiya on myeloid leucocytes is negative (that is, all the myeloid leucocytes fail to take the stain) in an acute case of typical epidemic encephalitis (with lethargy, ophthalmoplegia, and asthenia or fever), but is positive (that is, all the myeloid leucocytes take the stain) in any other disease, whether of infectious or noninfectious origin. This is true only of the peroxidase test as done by the copper method, which they believe is superior to other peroxidase methods in simplicity, in sensitivity, in constancy of color and its contrast with the unstained red cells, and in the durability of the reagents used. Fixation of the blood smears is unnecessary.

The technic of this reaction is as follows: The reagents used are three in number: 1. Solution A, consisting of 0.5 per cent copper sulphate solution. 2. Solution B is prepared by rubbing 0.2 gm. of benzidin with a few drops of water in mortar. Add 200 c. c. of water at room temperature and filter, and then add 4 drops of hydrogen peroxide (3 per cent). In a brown bottle this solution will last a year, although precipitation will begin to occur soon after preparation. 3. Solution C (counterstain) may be a 1.0 per cent aqueous solution of safranin, or neutral red, or carbolfuchsin (one part in five).

To a fresh, dry blood smear apply solution A. Pour off most of it and apply solution B for two minutes. Then wash thoroughly with water. The peroxidase granules of the leucocytes stain a deep bluish green, which does not fade. For counterstaining do not rinse after pouring off the peroxidase stain, but add solution C at once and let stand for two minutes before washing. The cytoplasm of the myeloid leucocytes stains blue by this method, whereas the lymphoid elements show no trace of blue or green but appear red because of their redstaining nucles. Copper salts are superior to any other salts.

During convalescence from encephalitis, the reaction changes from negative to positive. The oxidase reaction of Winkler and Schultze on myeloid leucocytes of the blood, over which the peroxidase reaction is an improvement, is always positive in all diseases, including acute epidemic encephalitis. Animal experiments have located the brain area controlling the peroxidase reaction in the corpora striata, puncture of which or severe inflammation of which, produces a negative peroxidase reaction.

In prognosis, the peroxidase reaction is valuable, being more favorable when positive and less favorable when negative. The length of staining time with solution B necessary to produce a positive reaction is directly proportional to the gravity of the prognosis.

Recovery of Treponema pallidum from the Spinal Fluid of a Patient with Syphilitic Meningitis of the Neurorecurrence Type.—Jarold E. Kemp and Alan M. Chesney (*Bulletin of the Johns Hopkins Hospital,* March, 1925) report a case of syphilitic meningitis of the neurorecurrence type in which treatment was begun while the patient was in the seronegative primary stage of the disease, and about fourteen days after the appearance of the lesion. None of the usual secondary manifestations occurred at any time. Four months after the last treatment the symptoms of an acute syphilitic meningitis first appeared and one month later the patient applied for treatment. At this time three c.c. of his spinal fluid, which was positive to all tests, was inoculated into a rabbit's testicle. About sixty-eight days later the animal developed an orchitis and fourteen days later, or eighty-two days after inoculation, specimens of Treponema pallidum were demonstrated in the affected testicle.

Medicolegal Notes.

LICENSES TO PRACTISE CHIROPRACTIC IN NEW JERSEY WITHOUT EXAMINATION TO CERTAIN WORLD WAR VETERANS

The New Jersey Court of Errors and Appeals holds, Kinlin v. State Board of Medical Examiners of New Jersey, 127 Atl. 522, that it was the intention of the New Jersey Legislature, by Act March 22, 1923, (P. L. p. 343) § 1, amending Act March 31, 1921 (P. L. p. 268) § 11, to provide that any person who served in the military or naval forces of the United States in the World War, and who on March 22, 1923, was a student or in training in a legally incorporated college of chiropractic under the jurisdiction of the federal Board of Vocational Training, upon being graduated from any such institution and furnishing evidence thereof satisfactory to the board of medical examiners, should without any further qualifications or requirements be entitled to have a license, issued by the board, to practise chiropractic.

AGREEMENT TO PAY FOR PRIOR TREATMENT TO ADULT SON IN CONSIDERATION OF FURTHER TREATMENT HELD NOT WITHIN STATUTE OF FRAUDS

In an action for $188 for treating defendant's adult son and his son's wife, it appeared that $102 was for treatment without any prior promise of defendant to pay therefor, and $86 was for treatment after the physician had informed defendant that he would not treat his son any further unless he would agree to pay not only for his services from that date, but also the old bill of $102, to which, he alleged, the defendant agreed.

The Texas Court of Civil Appeals held, Evans v. Shaw, 268 S. W. 1037, that as to the $86, plaintiff, in treating defendant's son, was extending credit to defendant, and defendant's obligation to pay was an original primary obligation. It was defendant's own debt and the promise to pay for the services rendered after the promise was made did not come within the statute of frauds. As to this plaintiff was entitled to recover.

As to the $102 it was held that plaintiff extended credit solely to the son, and this much of the account was a debt against him alone, and continued such for nearly a year, up to the time of defendant's verbal promise to pay it. The question was whether defendant's promise to pay this part of the debt was within the statute of frauds. The son was twenty-five years old, married, not dependent upon his father, nor a member of his family, and there was no legal obligation upon defendant's part to furnish him medical treatment; "but," the court said, "at the time of said conversation between appellant and appellee (defendant and plaintiff), appellant's son was a very sick man, and died a few days later. The son was in a helpless condition, unable on his own responsibility to secure treatment by appellee. There was a moral obligation and duty on the part of appellant to secure such treatment, and no doubt appellant felt very keenly this moral obligation on his part, and so, for the purpose, not primarily of paying or securing his son's debt, but to subserve a purpose of his own—the performance of this moral obligation to his son—he agreed unconditionally to pay not only for future treatments, but also the old bill of $102."

There is a conflict in the decisions, in Texas and the other states, as to whether or not a promise to pay the debt of another is within the statute of frauds. Under the settled rule in Texas, however, the court held that defendant's promise having been made to subserve a purpose of his own, and not primarily to settle his son's debt, such promise was not within the statute of frauds, and created a primary obligation on defendant's part for the $102, as well as for the future treatments. Judgment for plaintiff was affirmed.

NECESSITY FOR LICENSE—"PRACTISING MEDICINE" DEFINED

The West Virginia Supreme Court of Appeals holds, State v. Morrison, 127 S. E. 75, that one who opens an office and announces to the public in any way that he is ready to treat the sick and afflicted, and has actually treated cases of paralysis, constipation, rheumatism, neuritis, sick headache, kidney trouble, lumbago, liver trouble and divers other diseases by adjustment of the segments of the spinal column according to the chiropractic method of treating human ailments and infirmities, is "practising medicine and surgery," as defined by section 12, c. 11, Acts 1915. The provisions of that statute requiring examination of and license to a person before he can lawfully practise medicine and surgery as therein defined, and imposing a penalty for practising without such license, are held to be applicable to a chiropractor who treats human ailments and infirmities for reward as such, and are not in contravention of sections 1 and 10, article 3, of the state Constitution, nor of the federal Fourteenth Amendment.

The court quotes with approval the definition in a similar case, Commonwealth v. Zimmerman, 221 Mass., 184, as to what constitutes the practice of medicine, as follows: "Medicine relates to the prevention, cure and alleviation of disease, the repair of injury, or treatment of abnormal or unusual states of the body and their restoration to a healthful condition. It includes a broad field. It is not confined to the administering of medicinal substances or the use of surgical or other instruments. It comprehends a knowledge, not only of the functions of the organs of the human body, but also of the diseases to which these organs are subject, and of the laws of health and the modes of living which tend to avert or overcome disease, as well as of the specific methods of treatment that are most effective in promoting cures."

KANSAS PRIVILEGE STATUTE HELD NOT APPLICABLE TO WORKMEN'S COMPENSATION PROCEEDINGS

The Kansas Supreme Court holds, Doty v. Crystal Ice & Fuel Co., 235 Pac. 96, that the provision of the Kansas Code, R. S. 60-2805, to the effect that physicians are incompetent to testify concerning certain matters does not create a privilege personal to the physician.

It is also held that the purpose of the Workmen's Compensation Act, the nature of the inquiry to determine liability, and the statute itself (R. S. 44-515, 44-519) preclude the application of R. S. 60-2805, in so far as it relates to the testimony of physicians, from having any application to claims for compensation under the Workmen's Compensation Act.

INFECTION FROM REMOVAL OF PIMPLE WITH INFECTED INSTRUMENT HELD ACCIDENT

The Indiana Appellate Court holds, James v. State Life Ins. Co., 147 N. E. 533, that the death of an insured from infection caused by the removal by a barber of a pimple from the insured's face with an infected blackhead eradicator resulted from bodily injury sustained directly through external, violent and accidental means within the meaning of an insurance policy.

A CERTIFICATE HELD NOT A "PRESCRIPTION"

The Texas Court of Criminal Appeals holds, in a prosecution for transporting intoxicating liquor, Gaudy v. State, 268 S. W. 951, that a document from a physician stating: "This is to certify that Mr. —— has had the flu and I recommend that he should use strychnine or whiskey as a stimulant for his heart" is not a prescription.

Some Indications for Splenectomy*

JOHN B. DEAVER, M.D.
Philadelphia, Pa.

Our present limited knowledge of the functions of the spleen, coupled with the fact that it is an organ not essential to life, raises the pertinent question of, Why the spleen? The answer is neither easy nor clear.

Among the various hypotheses offered with regard to the function of the spleen, those receiving greatest consideration are that the spleen as a blood forming organ is closely related to the bone marrow, this relationship being dependent upon a hormone elaborated by the spleen and having a stimulating effect on bone marrow. The rôle of the spleen in the formation of red blood cells in embryonic life is generally admitted, but normally after birth this activity is supposed to stop, the formation of red cells in the postnatal spleen being a reversion to embryonic conditions, in other words a pathological process, or perhaps the response to a pathological process somewhere else. As to the fate of the red blood cells in the spleen, the worn out cells are supposed to be destroyed by the spleen and the liberated hemoglobin may be carried to the liver and there transformed into bilirubin, or their destruction may be partially brought about by phagocytosis, but the precise manner in which the destruction is completed is not known. According to some investigators the liberated hemoglobin may be manufactured into bilirubin in the spleen itself.
